In the past 40 years we have witnessed additional important developments. Gram-positive bacteria, including coagulase-negative staphylococci, *S. aureus*, enterococci, and streptococci, have reemerged as significant pathogens in hospitalized patients.[219,260,319,628] Antimicrobial-resistant bacteria, such as methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci (VRE), and gram-negative bacilli resistant to third-generation cephalosporins, aminoglycosides, carbapenems, and quinolones have become especially problematic.[293,348,543] Although MRSA has received the most attention in the media, gram-negative pathogens, such as carbapenemase-producing Enterobacteriaceae, *Burkholderia*, *Stenotrophomonas*, and *Acinetobacter* are even more problematic because they are resistant to most (or even all) available antibiotics and the pipeline of new active agents is virtually nonexistent.[73] Overutilization of antibiotics is in part responsible for the continued increase in *Clostridium difficile* infections,[120] but the clonal spread of more virulent strains of *C. difficile* (NAP-1) is a major problem for

both adults and children.[401,436,667] Multiple studies have documented an increase in *C. difficile* infection in hospitalized children over the past decade.[343,492,724] As increasing numbers of severely ill and immunosuppressed children are cared for in hospitals, the incidence of fungal infection has increased dramatically, especially infection caused by *Candida* and *Aspergillus*.[1,219,224,435] Health care–associated acquisition of common respiratory viruses, such as RSV, parainfluenza virus, and adenovirus, can cause severe, sometimes lethal pneumonia in these patients. Finally, the potential for health care–associated infection caused by bloodborne pathogens, such as the human immunodeficiency virus (HIV), hepatitis B, and hepatitis C, among patients as well as health care workers is well recognized.*

In the past decade, health care–associated infections have been viewed through the lens of efforts to improve the quality and safety of health care.[315,351] A majority of states require public reporting of institutional rates of health care–associated infections, and the Center for Medicare and Medicaid Services (CMS) requires facilities providing care for Medicare and Medicaid patients to report rates of health care–associated infections, with comparative data available for public viewing on the CMS Hospital Compare website.† These infections are broadly recognized as important contributors to the preventable harms that occur to patients as a consequence of health care, and a consortium of leading professional societies and governmental groups has issued a call to action for their elimination.[100] Supporting this goal is the fact that initiatives to reduce health care–associated infections have been among the most prominent of the patient safety success stories.[118,533,534] A variety of multicenter collaborative networks are actively working on prevention of health care–associated infections in children[302,452,592]; and, in 2011, a new national effort, the "Partnership for Patients" led by the U.S. Department of Health and Human Services, was launched with a goal of a 40 percent reduction in preventable harms, including health care–associated infections, by the end of 2013.[434] In addition, the U.S. Department of Health and Human Services has developed a "National Action Plan to Prevent Healthcare-Associated Infections: Roadmap to Elimination" that includes components for acute care hospitals, ambulatory surgical centers, end-stage renal disease facilities, and long-term care facilities.‡ Much of the information in the plan is relevant to the care of children in health care facilities, although it does not address pediatrics specifically.

Subsequent sections of this chapter expand on the themes just outlined by describing health care–associated infections due to spread of communicable infections in health care facilities, infections related to invasive devices and procedures, infections caused by special pathogens and occurring in special populations, as well as the components of programs to prevent these infections and to optimize antimicrobial stewardship.

HEALTH CARE–ASSOCIATED INFECTIONS DUE TO SPREAD OF COMMUNICABLE INFECTIONS IN HEALTH CARE FACILITIES

General Principles

Health care–associated infections that occur as a result of spread of communicable infections common in the community are a major concern for all facilities providing health care to children. Several principles regarding the epidemiology of these infections, modified from those initially published by Hall,[268] are summarized here. First, their appearance and spread on the wards parallels closely the disease activity in the community. Second, exposure to these pathogens generally results in infection in any host who lacks specific immunity; consequently, a susceptible child is at risk regardless of the nature or severity of his or her underlying disease or medical treatment. Third, these infections are often more severe in patients who have underlying diseases (e.g., prematurity, pulmonary or cardiac disease) or who are immunocompromised. Fourth, children hospitalized as a result of the community-acquired infections comprise the most important reservoir for microorganisms causing these infections, but mildly symptomatic or asymptomatically colonized adult caregivers and visitors may be important reservoirs for some agents (e.g., RSV, pertussis). Fifth, prevention is dependent primarily on the timely implementation of and compliance with isolation precautions designed to interrupt the modes of transmission of the microorganisms involved. In some situations, other interventions are also indicated, such as chemoprophylaxis for infants exposed to pertussis and immune globulin for high-risk individuals exposed to measles. Finally, unless postdischarge surveillance is performed, the frequency of these infections will be underestimated given short hospital stays and the fact that some infections (e.g., *C. difficile* infection) may be incubating at the time of discharge and manifest only after the child returns home.

Modes of Transmission

Airborne transmission involves spread of microorganisms by droplet nuclei, which are small particles (<5 μm) generated by the desiccation of larger respiratory droplets, especially those expelled by coughing. Because they are extremely light, droplet nuclei can travel over very long distances on air currents. Because they are so small, droplet nuclei can remain suspended in inhaled air, evading the mechanical host defenses of the upper respiratory tract, to reach the distal airways and alveoli.[464] Diseases spread by airborne transmission of respiratory droplet nuclei include measles, tuberculosis, smallpox, and, under certain circumstances, influenza and varicella.[158,381,466,550,699]

Droplet transmission involves transfer of microorganisms by large respiratory droplets, such as those generated by coughing or sneezing, which typically travel short distances in the air before settling. Important pathogens

spread by this route include *Bordetella pertussis*, *Neisseria meningitidis*, and group A streptococci.

Contact transmission is the principal mode of transmission for most health care–associated infections. Direct contact transmission involves physical contact between a person harboring the microorganism and a susceptible host, such as a caregiver with a herpetic whitlow who transmits the virus to a neonate. Indirect contact transmission involves transfer of microorganisms via an intermediary person, object, or surface. The hands of caregivers are a common source for indirect contact transmission,[77] but fomites and contaminated environmental surfaces are also important for certain pathogens (e.g., RSV, *C. difficile*, MRSA, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, norovirus).[507,695]

Endogenous infection (or autoinfection) is caused by a patient's own colonizing flora, usually as a consequence of host defenses that are compromised by severe underlying disease, immunosuppressive therapy, or invasive devices and procedures. Endogenous infections may be caused by microorganisms that are a part of the "normal" microbiome (e.g., coagulase-negative *Staphylococcus*) or that are acquired from exposure to the health care environment, usually by indirect contact transmission, and become persistent colonizers (e.g., VRE). These infections can be considered as a special case of contact transmission.

Common vehicle (common source) transmission involves the widespread dissemination of a microorganism to many persons via a contaminated item or substance. Examples include recent outbreaks of hepatitis B and C due to blood contamination of reused items[114,265] and outbreaks caused by nonenteric gram-negative bacilli, such as *P. aeruginosa*, that thrive in medications, solutions, or wet equipment and are relatively resistant to preservatives, antiseptics, and disinfectants.

Vector transmission of microorganisms either on (extrinsic) or within (intrinsic) insects is possible but rare in hospitals.[46,122,220]

Finally, some infections may be spread by more than one mode of transmission. For example, varicella zoster virus may be spread by airborne and contact transmission.

Standard and Transmission-Based Precautions

The Centers for Disease Control and Prevention's (CDC) Healthcare Infection Control Practices Advisory Committee (HICPAC) "Guideline for Isolation Precautions," describes strategies to prevent spread of communicable infections in health care facilities.[610] These strategies involve the use of Standard Precautions, which should be used for all hospitalized patients at all times, and Transmission-Based Precautions, which are used for patients with suspected or confirmed infections that may be transmissible to other patients or health care workers. Transmission-Based Precautions include Airborne Precautions, Droplet Precautions, and Contact Precautions, each of which is designed to interrupt one of the modes of transmission just described. The key components of Standard and Transmission-Based Precautions are outlined in Tables 243-1 and 243-2 and are described in more detail later in this chapter (see Infection Prevention and Control Programs in Health Care Facilities).

Respiratory Viruses

RSV is the most common health care–associated respiratory virus infection, especially among children younger than 2 years of age, because RSV infection accounts for a substantial number of hospital admissions in young children during epidemic periods.[78,269,375,601,681] In the absence of effective infection prevention and control programs, attack rates can be high because immunity after infection is short lived, inoculation of virus into the nose or eyes reliably leads to infection, infected children excrete high titers of virus in their copious secretions, and RSV survives for long periods in the environment.[267,269,271,274] Risk factors for health care–associated RSV infection are prematurity, heart and lung disease, immunocompromising conditions, and duration of hospitalization.*

The transmission of RSV can be markedly reduced by scrupulous attention to hand hygiene and the use of gloves and gowns when touching patients or their immediate inanimate environment.[261,379,676] Goggles and/or masks may be effective in further reducing the RSV attack rate in personnel.[7,232] However, it is unclear whether masks and eye protection are effective because they prevent direct deposition of respiratory droplets on the eyes or nose or merely because they reduce the likelihood that staff will rub their eyes or noses with contaminated hands. Covering only the nose and mouth with a mask is probably not very effective.[272] The HICPAC isolation guideline recommends use of Contact Precautions for care of hospitalized patients with RSV and does not require use of a mask.[610]

Some investigators have demonstrated that cohorting infected patients, combined with the use of barriers, can reduce spread of RSV.[189,356,415] However, it is not clear whether cohorting by clinical symptoms alone is effective or whether all admitted patients must be screened for RSV infection to identify children with minimal symptoms who may be excreting the virus. The added value of strict cohorting, as opposed to rigorous use of barrier precautions, has not been demonstrated. The role of palivizumab, either as routine seasonal prophylaxis or as postexposure prophylaxis for high-risk patients, has been examined in uncontrolled studies with generally positive but not conclusive results.[187,261,335,362,493]

Multidisciplinary programs to promote awareness of the potential for transmission of RSV and optimize the use of prevention measures, using all or various combinations of these strategies, have demonstrated effectiveness in reducing the incidence of health care–associated RSV infection.†

Health care–associated infections due to parainfluenza virus and human metapneumovirus are similar to RSV in their epidemiology and prevention.[269,459,479]

TABLE 243-1 **Standard Precautions***

A. Hand Washing

Wash hands after touching blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn.

Wash hands immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid transfer of microorganisms to other patients or environments.

It may be necessary to wash hands between tasks and procedures on the same patient to prevent cross contamination of different body sites.

Use a plain (nonantimicrobial) soap for hand washing.

Use an antimicrobial agent or a waterless antiseptic agent for specific circumstances (e.g., control of outbreaks or hyperendemic infections), as defined by the infection control program.

B. Gloves

Wear gloves (clean nonsterile gloves are adequate) when touching blood, body fluids, secretions, excretions, and contaminated items.

Put on clean gloves just before touching mucous membranes and nonintact skin.

Change gloves between tasks and procedures on the same patient after contact with material that may contain a high concentration of microorganisms.

Remove gloves promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient, and wash hands immediately to avoid transfer of microorganisms to other patients or environments.

C. Mask, Eye Protection, and Face Shield

Wear a mask and eye protection or a face shield to protect mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions.

D. Gown

Wear a gown (a clean nonsterile gown is adequate) to protect skin and prevent soiling of clothing during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.

Select a gown that is appropriate for the activity and amount of fluid likely to be encountered.

Remove a soiled gown as promptly as possible, and wash hands to avoid transfer of microorganisms to other patients or environments.

E. Patient Care Equipment

Handle used patient care equipment soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments.

Ensure that reusable equipment is not used for the care of another patient until it has been appropriately cleaned and reprocessed appropriately.

Ensure that single-use items are discarded properly.

F. Environmental Control

Ensure that the hospital has adequate procedures for the routine care, cleaning, and disinfection of environmental surfaces, beds, bedrails, bedside equipment, and other frequently touched surfaces, and ensure that these procedures are followed.

G. Linen

Handle, transport, and process used linen soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposure and contamination of clothing and that avoids transfer of microorganisms to other patients and environments.

H. Occupational Health and Bloodborne Pathogens

Take care to prevent injuries when using needles, scalpels, and other sharp instruments or devices; when handling sharp instruments after procedures; when cleaning used instruments; and when disposing of used needles.

Never recap used needles or otherwise manipulate them using both hands or any other technique that involves directing the point of a needle toward any part of the body; rather, use either a one-handed "scoop" technique or a mechanical device designed for holding the needle sheath.

Do not remove used needles from disposable syringes by hand, and do not bend, break, or otherwise manipulate used needles by hand.

Place used disposable needles and syringes, scalpel blades, and other sharp items in appropriate puncture-resistant containers, which are located as close as practical to the area in which the items were used, and place reusable syringes and needles in a puncture-resistant container for transport to the reprocessing area.

Use mouthpieces, resuscitation bags, or other ventilation devices as an alternative to mouth-to-mouth resuscitation methods in areas where the need for resuscitation is predictable.

I. Patient Placement

Place a patient who contaminates the environment or who does not (or cannot be expected to) assist in maintaining appropriate hygiene or environmental control in a private room.

If a private room is not available, consult with infection control professionals regarding patient placement or other alternatives.

*Standard Precautions apply to all patients regardless of their diagnosis or presumed infection status. Standard Precautions apply to any planned or potential contact with: (1) blood; (2) all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; (3) nonintact skin; and (4) mucous membranes.

From Siegel JD, Rhinehart E, Jackson M, et al. *Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings 2007.* Centers for Disease Control and Prevention, Healthcare Infection Control Practices Advisory Committee, 2007. Available at http://www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html. Accessed October 24, 2012.

Health care–associated influenza is a common cause of intercurrent fever in hospitalized children during epidemic periods,[270,681] and outbreaks in neonatal ICUs have been described.[156,471,686] Asthma was identified as a risk factor for health care–associated seasonal influenza.[378] Although the 2009-2010 pandemic of H1N1 influenza raised concerns about the potential for increased spread of influenza in health care facilities, the risk for transmission among hospitalized children appeared no different than for seasonal influenza,[209,504] perhaps because of

TABLE 243-2 Transmission-Based Precautions*

Airborne Precautions

A. Patient Placement

Place the patient in a private room that has (1) monitored negative air pressure in relation to the surrounding areas; (2) 6 to 12 air changes per hour; and (3) appropriate discharge of air outdoors or monitored high-efficiency filtration of room air before the air is circulated to other areas in the hospital.
Keep the room door closed and the patient in the room.
When a private room is not available, place the patient in a room with a patient who has active infection with the same microorganism, unless otherwise recommended, but with no other infection.
When a private room is not available and cohorting is not desirable, consultation with infection control professionals is advised before patient placement.

B. Respiratory Protection

Wear respiratory protection when entering the room of a patient with known or suspected infectious pulmonary tuberculosis.
Susceptible persons should not enter the room of patients known or suspected to have measles (rubeola) or varicella (chickenpox) if other immune caregivers are available.
If susceptible persons must enter the room of a patient known or suspected to have measles or varicella, they should wear respiratory protection.
Persons immune to measles or varicella need not wear respiratory protection.

C. Patient Transport

Limit the movement and transport of the patient from the room to essential purposes only.
If transport or movement is necessary, minimize patient's dispersal of droplet nuclei by placing a surgical mask on the patient, if possible.

D. Additional Precautions for Preventing Transmission of Tuberculosis

Consult the CDC "Guidelines for Preventing the Transmission of Tuberculosis in Health-Care Facilities" for additional prevention strategies.

Droplet Precautions

A. Patient Placement

Place the patient in a private room.
When a private room is not available, place the patient in a room with a patient(s) who has active infection with the same microorganism, but with no other infection.
When a private room is not available and cohorting is not achievable, maintain spatial separation of at least 3 feet between the infected patient and other patients and visitors.
Special air handling and ventilation are not necessary, and the door may remain open.

B. Mask

Wear a mask when working within 3 feet of the patient. (Logistically, some hospitals may want to implement the wearing of a mask to enter the room.)

C. Patient Transport

Limit the movement and transport of the patient from the room to essential purposes only.
If transport or movement is necessary, minimize patient dispersal of droplets by placing a surgical mask on the patient, if possible.

Contact Precautions

A. Patient Placement

Place the patient in a private room.
When a private room is not available, place the patient in a room with a patient(s) who has active infection with the same microorganism, but with no other infection.
When a private room is not available and cohorting is not achievable, consider the epidemiology of the microorganism and the patient population when determining patient placement; consultation with infection control professionals is advised before patient placement.

B. Gloves

Wear gloves (clean nonsterile gloves are adequate) when entering the room.
During the course of providing care for a patient, change gloves after having contact with infective material that may contain high concentrations of microorganisms (fecal material and wound drainage).
Remove gloves before leaving the patient's environment and wash hands immediately with an antimicrobial agent or a waterless antiseptic agent.
After glove removal and hand washing, ensure that hands do not touch potentially contaminated environmental surfaces or items in the patient's room to avoid transfer of microorganisms to other patients or environments.

C. Gown

Wear a gown (a clean, nonsterile gown is adequate) when entering the room if you anticipate that your clothing will have substantial contact with the patient, environmental surfaces, or items in the patient's room or if the patient is incontinent or has diarrhea, an ileostomy, a colostomy, or wound drainage not contained by a dressing.
Remove the gown before leaving the patient's environment.
After gown removal, ensure that clothing does not contact potentially contaminated environmental surfaces to avoid transfer of microorganisms to other patients or environments.

D. Patient Transport

Limit the movement and transport of the patient from the room to essential purposes only.
If the patient is transported out of the room, ensure that precautions are maintained to minimize the risk for transmission of microorganisms to other patients and contamination of environmental surfaces or equipment.

E. Patient Care Equipment

When possible, dedicate the use of noncritical patient care equipment to a single patient (or a cohort of patients infected or colonized with the pathogen requiring precautions) to avoid sharing between patients.
If use of common equipment or items is unavoidable, then adequately clean and disinfect them before use for another patient.

F. Additional Precautions for Preventing the Spread of Vancomycin Resistance

Consult the HICPAC report on preventing the spread of vancomycin resistance for additional prevention strategies.

*Transmission-Based Precautions are followed, when indicated, in addition to Standard Precautions.

From Siegel JD, Rhinehart E, Jackson M, et al. *Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings 2007.* Centers for Disease Control and Prevention, Healthcare Infection Control Practices Advisory Committee, 2007. Available at http://www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html. Accessed October 24, 2012.

heightened awareness and more rigorous use of barrier precautions.

The modes of transmission of influenza have not been precisely defined. Although direct, indirect, and droplet contact are likely to be important, the potential for airborne transmission and the relative contributions of these various modes of transmission in health care facilities, as well as potential differences in transmission of seasonal versus pandemic influenza, remain unclear.[101] For seasonal influenza, the CDC recommends use of Droplet Precautions, with use of respiratory protection equivalent to a fitted N95 filtering facepiece respirator or equivalent N95 respirator during aerosol-generating procedures.*

Annual influenza vaccination of high-risk individuals and health care workers is important to limit the impact of transmission in health care facilities.[117] Issues related to vaccination of health care workers against influenza are discussed later in this chapter (see Infection Prevention and Control Programs in Health Care Facilities). Antiviral medications are an adjunct to vaccination, both for treatment to reduce viral shedding and chemoprophylaxis to prevent infection after exposure.[214]

Health care–associated adenovirus infections occur sporadically throughout the year, and outbreaks of respiratory tract infection and pharyngoconjunctival fever among hospitalized children have been described.† Outbreaks in ICUs and units caring for immunocompromised patients have been associated with severe disease and substantial mortality.[432,619,708] In addition to direct and indirect contact, adenovirus may be spread by droplet contact, necessitating the use of Droplet and Contact Precautions.

Health care–associated coronavirus infections may be more common than recognized.[231] Rhinovirus infections are generally mild, although serious lower tract disease has been documented in children with underlying disorders.[130] Standard Precautions are sufficient as a control measure in most situations.

Pertussis

Outbreaks of pertussis in hospitals and chronic care institutions are well documented.‡ In many situations, health care workers were responsible for spreading pertussis to hospitalized children.[115,129,360,396,674] The beneficial impact, but high cost, of controlling the intrahospital spread of pertussis was illustrated during a large community-wide epidemic of pertussis in Cincinnati in 1993.[132]

Prevention of health care–associated pertussis is dependent on the appropriate isolation of children in whom the infection is suspected, use of Droplet Precautions, antimicrobial treatment of confirmed cases to minimize the potential for transmission, and chemoprophylaxis of exposed individuals.[18,610] Hospital staff who present with symptoms suggesting pertussis must be evaluated and treated promptly, and infected individuals should be excluded from work for at least the first 5 days of the recommended course of treatment. Health care workers should receive booster doses of pertussis vaccine (in the form of Tdap) to help prevent transmission in health care facilities.[117]

Gastrointestinal Viruses

Rotavirus is a common cause of endemic and epidemic health care–associated gastrointestinal virus infection.* The risk for health care–associated infection is closely associated with hospitalization during seasonal outbreaks, young age, and the length of hospitalization.[86,143,178,683] The risk for transmission from infected children is enhanced because infected children may shed the virus in their stool for many days after symptoms resolve, asymptomatically infected patients also may shed virus, and the virus can survive for extended periods on environmental surfaces.[29,143,233,582,712]

The primary mode of transmission is indirect contact via the contaminated hands of caregivers, and the scrupulous adherence to Contact Precautions and appropriate disinfection of environmental surfaces is critically important.[619,688] The use of rotavirus vaccine appears to have decreased the risk for health care–associated rotavirus concomitant with reductions in the numbers of children hospitalized due to community-acquired infection.[25]

Health care–associated norovirus infection—most often due to genogroup II.4 that can cause more severe disease—is a major problem, although wards with elderly populations have been affected more significantly than pediatric wards.[180,431] Contamination of environmental surfaces is particularly common and contributes to transmission.[465,507] A HICPAC isolation guideline recommends use of Contact Precautions and appropriate disinfection of environmental surfaces, with additional recommendations to be considered in outbreak situations.[411]

Other intestinal viruses have been documented to cause endemic and epidemic nosocomial gastrointestinal infection, including enteric adenoviruses,[155,354] caliciviruses,[632] astroviruses,[177,361] and toroviruses.[318] Contact Precautions should be used to prevent transmission of these enteric pathogens.[610]

Clostridium difficile

Toxin-producing *C. difficile* acquired in the community may be spread in health care settings, although this is difficult to distinguish from spread of *C. difficile* from reservoirs in the health care facility (i.e., from infected patients or the health care environment). *C. difficile* infection is discussed later in this chapter (see Health Care–Associated Infections Related to Special Pathogens).

Other Gastrointestinal Bacteria

Gastrointestinal bacterial pathogens, such as *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Escherichia coli*, and *Vibrio*

*Centers for Disease Control and Prevention: http://www.cdc.gov/flu/professionals/infectioncontrol/healthcaresettings.htm.
†References 213, 246, 475, 523, 530, 619, 643, 708.
‡References 115, 215, 360, 396, 602, 635, 656, 674.

*References 86, 155, 250, 546, 559, 622, 683.

cholerae, may cause outbreaks of health care–associated diarrhea in areas where gastrointestinal infections caused by these organisms are endemic.* However, they are so rare in modern health care facilities that, in the absence of an outbreak, the yield of routine stool cultures in the evaluation of health care–associated diarrhea is extremely low.[79,148,722]

Varicella Zoster Virus

Outbreaks of health care–associated varicella in hospitals have been documented in numerous reports.[228,264,381,588] These reports demonstrate conclusively that varicella can be transmitted by the airborne route, although spread via direct and droplet contact may well be more efficient. In addition, a study that used polymerase chain reaction (PCR) assay detected airborne virus in the hospital rooms of patients with active infection and in air samples obtained in the hallway just outside the patients' negative-pressure isolation rooms.[583]

Transmission of varicella can be minimized if infected patients are cared for using Airborne Precautions in single rooms with separate exhaust systems and negative air pressure relative to the hallway.[26,610] Contact Precautions to prevent direct and indirect contact transmission (gloves and gowns) are also important. Infected persons are infectious for 24 to 48 hours before distinctive symptoms and signs appear, so prompt recognition and isolation of patients and visitors who may be in the contagious phase of varicella is critical. Caregivers who are not immune to varicella should not care for such patients.

Options for postexposure prophylaxis, including passive immunization and use of varicella vaccine and acyclovir, are discussed in the American Academy of Pediatrics' *Red Book*.[19] Hospitalized exposed children should remain in isolation from day 8 to day 21 after exposure. If passive immunization is administered, isolation should be continued until day 28 after exposure.[19]

The use of varicella vaccine has diminished the risk for health care–associated varicella by decreasing the number of children hospitalized with varicella, reducing the size of the pool of susceptible children in hospital wards, and providing protective immunity to health care workers who did not have a history of prior infection.[117] However, incompletely vaccinated children and health care workers, as well as persons who develop breakthrough infection, pose a risk for transmission.

Cytomegalovirus

Two studies using molecular typing techniques have documented probable patient-to-patient spread of cytomegalovirus (CMV) in a neonatal ICU and a chronic care unit.[176,631] In both situations, the infected children had been in close proximity and were cared for by common caregivers for extended periods of time. Nonetheless, the risk for CMV transmission from infected patients to health care workers appears to be very low. A meta-analysis of a number of studies that have examined the risk for CMV among pediatric nurses indicates that CMV infection in this population occurs at a rate that is comparable to control populations (women of comparable age who are not nurses).[6] A subanalysis of these data suggests that nursery nurses may have a slightly higher rate of infection than control populations.[6] However, studies of CMV infection in nursery nurses that involved molecular typing of CMV isolates have shown that the infected nurses did not acquire CMV from the infants in their care[6] and presumably contracted their infections from children in their own households, through sexual contact, or from other community sources.

Given the frequency of asymptomatic CMV excretion in children (for example, approximately 1% of newborns excrete the virus), health care workers should assume that any child may be excreting virus and should practice hand hygiene and use of Standard Precautions as a part of routine patient care.[610] Additional interventions are not indicated, and pregnant staff need not be given special assignments.

Herpes Simplex Virus

Health care–associated transmission of herpes simplex virus (HSV) type 1 to neonates has been confirmed through studies using molecular typing.[277,395,579,678] Direct contact transmission from a hospital worker with herpes labialis and indirect contact transmission from one infected neonate to another were the most likely routes, although transmission from an asymptomatic parent or caregiver was possible. Health care–associated HSV infections among health care workers, patients, and family members have also been described in ICUs.[5,521] Herpetic whitlow has been observed among nurses, presumably as a result of direct transmission during suctioning of oral and respiratory secretions from infected patients.[5] The use of Standard Precautions, particularly the use of gloves during contact with oral and respiratory sections and hand hygiene, is adequate to prevent transmission of HSV.[510]

Measles, Mumps, and Rubella Viruses

Transmission of measles in health care facilities remains a threat, and hospitals have the potential to serve as niduses for community-wide infection.[72,116,127] Measles is transmitted by airborne droplet nuclei, as demonstrated by an outbreak in a pediatrician's office.[550]

Prevention of health care–associated measles hinges on the prompt recognition of infected or potentially infected patients and placement of these patients in isolation rooms with negative air pressure relative to the hallway.[610] Prophylactic vaccination of exposed susceptible individuals within 3 days of the exposure reliably prevents measles, whereas administration of immune globulin within 3 days attenuates disease but does not guarantee that the exposed individual will not develop contagious infection.[16] To avoid outbreaks of measles among health care workers, health care facilities should require new employees involved in patient care to provide evidence of immunity or appropriate vaccination or to

*References 48, 94, 99, 195, 244, 290, 334, 446, 545, 570, 597, 641, 677.

receive vaccination with either measles vaccine or MMR (measles, mumps, rubella) vaccine.[117,357]

Outbreaks of health care–associated mumps and rubella have been reported less commonly than measles.[291,527,642,709] The primary concern with regard to spread of both of these infections relates to potential complications in health care workers—mumps orchitis in adult males and rubella in pregnant staff. Information regarding the transmission of both of these viruses is limited, but it probably occurs primarily via droplet contact. Droplet Precautions should be observed during close contact with infected patients.[610] Transmission of mumps occurs before and within 5 days of parotitis onset, so isolation should be during this period.[364] Patients with congenital rubella syndrome may excrete large amounts of virus in their urine and respiratory secretions for extended periods. Consequently, gowns and gloves should be worn for contact with these patients for the first year of life unless nasopharyngeal and urine cultures are negative by 3 months of age.[610] There is no known effective postexposure prophylaxis for mumps or rubella-exposed individuals.

As with prevention of measles, new employees involved in patient care should provide evidence of immunity or appropriate vaccination or receive vaccination with MMR vaccine as a condition of employment.[117]

Parvovirus B19

The wide spectrum of disease caused by parvovirus B19, coupled with well-documented health care–associated outbreaks of infection, has fueled efforts to understand the transmission and control of this virus in hospitals. An experimental study of acute parvovirus B19 infection in normal adults detected virus in respiratory secretions during a period of viremia and systemic symptoms 6 to 13 days after inoculation.[28] Detectable virus in respiratory secretions disappeared as viremia and systemic symptoms diminished, and virus was not demonstrable in respiratory secretions when rash, arthralgias, and arthritis occurred several days later.[28] From studies of parvovirus B19 infection in health care facilities, it is apparent that the virus can be transmitted by acutely infected patients, probably owing to high levels of virus in their blood and respiratory sections.* The risk for transmission from chronically infected, immunocompromised patients is less clear; however, from one report it appears that these patients can transmit infection.[407]

The mode of transmission is not clear but probably involves direct or indirect contact with respiratory secretions or droplet transmission. Therefore, Droplet Precautions should be maintained during contact with infected patients, and gloves should be worn when handling fomites contaminated with respiratory secretions.[610]

Hepatitis A Virus

In the prevaccination era, hepatitis A virus caused rare but large epidemics in health care facilities.[37,192,347,486,693] Mildly symptomatic children who excrete virus in their stool can cause widespread transmission, and many secondary cases may occur before the infection is detected and contained.

Controlling a health care–associated hepatitis A outbreak is difficult and may require the assistance of the local health department. To limit the potential for indirect contact transmission, hospitalized infected children should be cohorted. Hand hygiene and use of barrier precautions should be emphasized to prevent direct and indirect contact transmission.[610] Postexposure prophylaxis, which may involve immune globulin or hepatitis A vaccination depending on age and underlying conditions, should be administered to all exposed, susceptible individuals.[17] Symptomatic health care providers should be furloughed until 1 week after the onset of symptomatic infection or until all susceptible persons have received immune globulin.[69]

Enteroviruses

Outbreaks of health care–associated enterovirus have been reported, most occurring in neonatal nurseries.*

Like for hepatitis A, hand hygiene and barrier precautions are of paramount importance to prevent transmission and cohorting of infected infants is prudent.[610] One report describes the value of early diagnosis using a PCR assay to successfully control measures.[34] The upper respiratory tract may be involved in acute enteroviral infection, but the use of masks by caregivers is not recommended.[610]

Tuberculosis

Health care–associated tuberculosis in pediatric patients occurs almost exclusively as a result of transmission of *Mycobacterium tuberculosis* from infected adults—parents, visitors, and health care workers—to other children and adults.† Probable transmission from infected children in health care settings has been described.[430,540] However, the risk for transmission from a child is very small because children infrequently have cavitary disease and consequently have fewer tubercle bacilli in their endobronchial secretions and because young children do not tend to generate aerosols of airborne droplet nuclei.[634] Nonetheless, transmission from children can occur as evidenced by extensive transmission from a 9-year-old child with bilateral cavitary disease.[158]

The risk for health care–associated tuberculosis in adult hospitals has been minimized by prompt recognition and treatment of pulmonary tuberculosis, adequate isolation of infectious patients in rooms with negative air pressure relative to the hallway, and proper use of personal protective equipment.[323] If rooms with appropriate ventilation are unavailable, alternative engineering solutions, such as well-placed and maintained ultraviolet lights, may be useful.[323] Personnel entering the rooms of infected patients should wear respiratory protection devices. for Occupational Safety and Health certification of N95 or better satisfy the CDC specifications for these devices.[323] These devices must be fit tested on the individuals using them according to the standards of the Occupational Health and Safety Administration (OSHA).[323] Prompt identification of tuberculosis in parents, visitors, and health care workers in hospitals caring for pediatric patients is critical to reducing the risk for health care–associated tuberculosis in children and is cost saving compared with conducting postexposure follow-up investigations.[153] Health care workers should be screened yearly for evidence of tuberculosis.[323]

Invasive Bacterial Infections

Health care–associated transmission of *Neisseria meningitidis* is rare.[141,200,560] Nonetheless, *N. meningitidis* is spread by droplet transmission and health care workers should use Droplet Precautions during the care of patients with suspected invasive meningococcal disease until the patient has completed 24 hours of parenteral antimicrobial therapy.[610]

On the other hand, microbiology laboratory workers have developed fatal disease after working with cultures of this microorganism.[104,111] Clinical and research microbiologists who might be exposed routinely to isolates of *N. meningitidis* should receive meningococcal conjugate vaccine, as well as booster doses every 5 years if they remain at increased risk.[117]

Health care–associated transmission of *Haemophilus influenzae* and *Streptococcus pneumoniae* has been a rare phenomenon,* and the risk has likely been diminished substantially with vaccination.

Invasive bacterial infections in neonates, including infections caused by *S. aureus*, group B streptococci, *Citrobacter* spp., and *Enterobacter sakazakii*, are discussed later in this chapter (see Health Care–Associated Infections in Special Populations).

Ectoparasites

A large number of outbreaks of scabies have been reported from a variety of health care institutions. The presence of crusted scabies, which is associated with defects in cellular immunity, increases the risk for transmission dramatically because of the large number of mites in these lesions.[387] Although health care–associated transmission of pediculosis is possible, the direct or indirect contact necessary to spread this infection (i.e., head-to-head contact or sharing of combs) is less likely in medical settings than at home.

Intestinal Helminths

Person-to-person transmission of *Enterobius vermicularis* (pinworm), *Strongyloides stercoralis*, *Hymenolepis nana*, and *Taenia solium* is possible because these microorganisms do not require an intermediate host and because the eggs or larvae excreted in the stool are infectious.[386] However, evidence for health care–associated transmission of these microorganisms is limited.[386]

HEALTH CARE–ASSOCIATED INFECTIONS RELATED TO INVASIVE DEVICES AND PROCEDURES

Health care–associated infections can occur from contact with intravascular catheters and infusions, respiratory therapy, instrumentation of the urinary tract, and surgical procedures. Children are at risk for other health care–associated infections related to medical treatments, including infections associated with receipt of blood products. To learn more about these infections, the reader is referred to the chapters in this text related to common bloodborne pathogens.

Infections Related to Intravascular Catheters and Infusions

Infections related to intravascular catheters may be local or systemic. Local infections may involve the catheter exit site, subcutaneous track of tunneled catheters, or subcutaneous pocket of an implanted catheter.[443,494] Phlebitis is a common local complication but is usually due to chemical or mechanical irritation and is less common in children than adults.[238] Suppurative thrombophlebitis is rare in children.[340] Bloodstream infections related to intravascular catheters can have serious complications, including development of endocarditis, septic thrombophlebitis, and infection at distal sites due to hematogenous seeding, and independently increase the length of stay and hospital cost.[202,443,494]

Clinical and surveillance definitions for bloodstream infections related to central venous catheters differ, although they are often used interchangeably (Tables 243-3 and 243-4).[300,443] *Catheter-related bloodstream infections* are clinical events that require investigation to establish the catheter as the definitive source of infection (i.e., through quantitative blood cultures, differential time to positivity, or culture of the catheter itself, if it is removed) (see Table 243-3).[443] For surveillance purposes, the term *central line–associated bloodstream infection* (CLABSI) is used by the CDC's National Healthcare Safety Network (NHSN) to capture primary bloodstream infections in patients with central lines (see Table 243-4).[300] This definition is simpler for surveillance purposes. There is growing concern that NHSN definitions may overestimate catheter-related infections in some patients with impaired mucosal integrity in which bacterial translocation may be an important component in the pathogenesis of bloodstream infections,[222] and efforts to develop modified definitions for this subgroup of patients are underway.[184] Readers should refer to the NSHN website for the latest updates in NHSN definitions and methodology.* Although the focus in this chapter is primarily on clinical events related to catheters, most epidemiologic

TABLE 243-3 Clinical Definitions for Intravascular Catheter-Related Infections

Infection	Diagnostic Criteria
Catheter colonization	Significant growth of ≥1 microorganism (>15 CFU) from the catheter tip, subcutaneous catheter segment, or catheter hub
Local infection	
Phlebitis	Induration, erythema, warmth, or pain/tenderness along the tract of a catheterized or recently catheterized vein
Exit site infection	Erythema, induration, or tenderness within 2 cm of the catheter exit site, with or without concomitant BSI
Tunnel infection	Tenderness, erythema, or site induration >2 cm from the catheter site along the subcutaneous tract of a tunneled (e.g., Hickman or Broviac) catheter, with or without concomitant BSI
Pocket infection	Purulent fluid in the subcutaneous pocket of a totally implanted intravascular catheter; often associated with spontaneous rupture and drainage or necrosis of the overlaying skin, with or without concomitant BSI
Bloodstream infection	
Infusate-related	Concordant growth of the same organism from the infusate and blood cultures (preferably percutaneously drawn) with no other identifiable source of infection
Catheter-related	Bacteremia/fungemia in a patient with an intravascular catheter with at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infections (i.e., fever, chills, and/or hypotension) and no apparent source for the BSI except the catheter. One of the following should be present: a positive semiquantitative (>15 CFU/catheter segment) or quantitative (>10^2 CFU/catheter segment catheter) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a >3:1 CFU/mL ratio of blood (catheter vs. peripheral); differential period of catheter culture versus peripheral blood culture positivity of >2 hr.

BSI, bloodstream infection; CFU, colony-forming unit.

data on bloodstream infections come from the use of surveillance definitions.

The vast majority of endemic catheter-associated bloodstream infections in children are associated with central venous catheters.[418] Peripheral venous catheters, especially catheters made with modern, nonthrombogenic materials, are rarely associated with bloodstream infections,[238,239,418,605] although presumably few data are systematically collected and the risk may be underestimated.[237,668] Peripheral arterial catheters have historically been associated with lower rates of infection compared with central venous catheters[193,230]; however, recent evidence among adult ICU patients suggests that rates of colonization and infection of these catheters may be

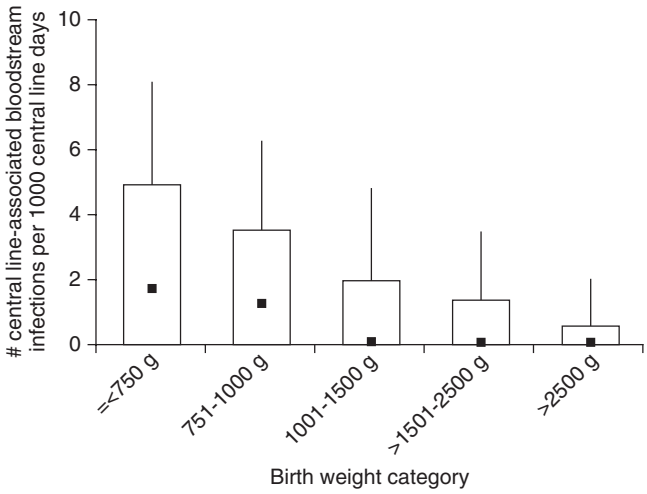

FIGURE 243-1 ■ Distribution of central line–associated bloodstream infection rates in level III neonatal intensive care units reported to the National Healthcare Safety Network (NHSN). Boxplots of the distribution of central line–associated bloodstream infection rates in neonatal intensive care units indicate the following: the solid square (■) represents the 50th percentile (median). The upper bound of the open vertical rectangle (□) represents the 75th percentile. The upper bound of the line extending above the open vertical rectangle represents the 90th percentile. The number of participating neonatal intensive care units in each of the birthweight classes ranged from 226 to 245. (Modified from Dudeck MA, Horan TC, Peterson KD, et al. National Healthcare Safety Network [NHSN] Report, data summary for 2010, device-associated module. *Am J Infect Control* 2011;**39**:798-816.)

similar to those observed for central lines.[350,406] The risk for bloodstream infection associated with peripheral arterial catheters appears to be highest in patients with femorally inserted arterial catheters.[206,403]

Given that the majority of infections occur in patients with central lines, the remainder of this section focuses on central venous catheters. National estimates of CLABSI rates are available through the CDC's NHSN during 2010. A recent NHSN report highlights data from 2473 hospitals from 49 states and the District of Columbia, of which 51 (2%) were dedicated children's hospitals.[194] Rates of bloodstream infection associated with central venous catheters in pediatric ICUs and inpatient wards and neonatal ICUs are displayed in Table 243-5 and Figure 243-1, respectively. Rates of infection are highest among children in specialty care areas, including hematology/oncology and bone marrow transplant, as well as pediatric rehabilitation.[194] Catheter-associated infections are also common among children with intestinal failure (or short-gut syndrome) who depend on parenteral nutrition. Among premature infants, infection rates are inversely proportional to birth weight. These data do not distinguish rates of infection associated with specific catheter types nor whether a specific catheter is the source of infection in patients who have multiple catheters in place concurrently.

The most commonly reported pathogens in nosocomial bloodstream infections include coagulase-negative staphylococci, *S. aureus*, enterococci, and *Candida* spp., although infections with gram-negative organisms may be increasing in some populations.[93,427,715] Pathogens associated with catheter infections in pediatric ICUs are available from 29 hospitals participating in the Children's Hospital Association Quality Transformation Network and are displayed in Table 243-6.[484] In this population, the majority of infections were caused by a single organism; gram-positive cocci were isolated most commonly, especially coagulase-negative staphylococci or enterococci. Of the *S. aureus* isolates, MRSA comprised nearly 50 percent. Gram-negative bacilli were identified in one third of cases and *Candida* spp. were found in 15 percent of cases. Antimicrobial resistance is a concern for all common pathogens isolated in bloodstream infections, including *S. aureus* and gram-negative bacilli.[92] Bloodstream infections due to VRE may be more prevalent in high-risk groups such as pediatric oncology patients and should be considered when selecting empirical therapy for bloodstream infections based on local epidemiology.[337] Nontuberculous mycobacteria and *Nocardia* spp. may also cause bloodstream infection.[10]

There are four major mechanisms for contamination of intravascular catheters: (1) migration of microorganisms colonizing the skin at the insertion site along the external catheter surface and into the blood vessel (extraluminal contamination); (2) contamination of the catheter or catheter hub through contact with hands of

health care workers (intraluminal contamination); (3) hematogenous seeding from another focus of infection; and (4) contamination of the infusate.[150,151,494,495] The first two mechanisms are most important and differ in their contributions to infection depending on the duration of catheterization.[536] Extraluminal contamination predominates in the first 10 days (likely related to contamination during insertion), whereas the potential for intraluminal contamination increases with duration of catheterization and is most common after 30 days (most likely due to contamination during routine catheter maintenance and use).[536] Contamination of infusates is relatively uncommon; however, a number of epidemics have been associated with contaminated intravenous infusions,[397,420,603] medications,[52,259,420,506] and blood products.[108]

Additional pathogenic determinants for bloodstream infection include catheter material, host factors leading to the formation of a fibrin sheath,[442] as well as intrinsic virulence of the microorganism. Catheters made of polyethylene or stiff plastics like polyvinyl chloride are less resistant to colonization in vitro and may lead to more blood vessel trauma than catheters made of polyurethane. Surface irregularities and the thrombogenicity of catheter material may also contribute to colonization and infection. Adherence properties of microorganisms are also critical. Production of an extracellular polymeric substance by organisms such as coagulase-negative staphylococci, *S. aureus*, and *P. aeruginosa* leads to formation of a microbial biofilm in which microorganisms can become embedded and proliferate relatively protected from host defenses and antimicrobial agents.[4,191,307,439] *Candida* spp. also routinely produce biofilms, particularly in the presence of glucose-containing fluids.[80]

The principal risk factors for catheter-related bloodstream infection include heavy colonization of the skin at the catheter exit site[150,151,495,537] or catheter hub,[170,394] longer duration of insertion (>3 days),[152,238,239] use of catheters with multiple lumens as opposed to single lumens,[135] and the presence of a mural or atrial thrombus.[150,151,495] Both the level and composition of nurse staffing have also been associated with bloodstream infections in adult surgical ICUs: low nurse-to-patient and regular nurse (as opposed to pool nurse)-to-patient ratios have been associated with a higher risk for bloodstream infection.[225,558]

Dedicated pediatric studies are limited; however, age younger than 2 years, duration of catheterization (i.e., presence of a catheter >7 days), and receipt of parenteral nutrition or blood transfusions have been independently associated with catheter-associated bloodstream infection in pediatric ICU patients.[173,201,484,719] A recent study of children at a tertiary care center found that catheter breakage was associated with significantly increased risk for bloodstream infection within 30 days of repair.[408] Additional novel risk factors identified in one study include presence of a gastrostomy tube, nonoperative cardiovascular disease, and ICU catheter placement.[719] Among pediatric oncology patients, placement of the catheter within 1 month and frequent platelet transfusions have been associated with increased risk for bloodstream infection.[337] Infusion of parenteral nutrition with lipids increases the risk for infection

with coagulase-negative staphylococci and *Candida* in neonates.[35,85,223,574]

Among central venous catheters, nontunneled (percutaneously inserted) catheters account for the majority of catheter-associated bloodstream infections whereas totally implantable catheters carry the lowest risk,* although these comparisons may be confounded by a number of factors, including age and underlying severity of illness.[35,85,313,711,718] Tunneled catheters carry a lower infection risk compared with nontunneled catheters, because presence of a cuff prevents migration of microorganisms into the catheter tract. Peripherally inserted central venous catheters (PICCs) are used commonly in pediatric patients and have been associated with fewer bloodstream infections than other central venous catheters[389]; however, duration of catheter dwell was shown to increase risk for PICC-associated infection among neonates, with a significant daily increase in risk after 35 days.[454,598] Rates of infection are similar between catheters placed in the umbilical vein versus artery.[371]

Catheter insertion site influences infection risk in adults, likely related to the density of local skin microorganisms, although comparisons of infection rates between nontunneled catheters placed in the subclavian, internal jugular, and femoral vein have only been made using observational data. A recent meta-analysis showed that catheters inserted into the internal jugular vein carry a higher risk for colonization and infection as compared with subclavian catheters, whereas femorally inserted catheters carry the highest risk, although the authors suggest that interpretation may be limited by study heterogeneity and limitations in study design.[511] In a Cochrane Review it was concluded that subclavian catheters were associated with less colonization and fewer thrombotic complications than femoral catheters in short-term catheterization but no difference was found between subclavian and internal jugular venous catheters.[56] Of note, femoral catheters have not been associated with higher colonization rates and infection in children, but further study may be warranted.[484,552]

To differentiate bloodstream infections that arise from the catheter as opposed to another site, paired blood cultures should be drawn from both the catheter and a peripheral vein before starting therapy.[443] If a peripheral sample cannot be obtained, at least two samples should be drawn through different catheter lumens. If the catheter is removed owing to suspected infection, catheter tip culture is recommended to determine whether it is colonized. Semiquantitative (roll-plate) or quantitative catheter culture techniques (luminal flushing or sonication) are the most reliable modalities and are preferred over qualitative broth cultures.[423,537,571,604,611]

Clinical criteria for definitive diagnosis of catheter-related bloodstream infections are displayed in Table 243-3 and require positive percutaneous culture results with concordant microbial growth from the catheter tip or catheter-drawn cultures that meet criteria for quantitative culture or differential time-to-positivity.[443] Quantitative blood cultures are the most accurate; however, the differential time-to-positivity technique can be almost as sensitive (provided the same volume of blood is used to inoculate both blood culture bottles) and is less labor intensive.[571] Because peripheral blood cultures are drawn less frequently in children, owing to difficulty in obtaining peripheral specimens or concerns about drawing large blood volumes, the catheter is often implicated presumptively if no other source of infection is identified: this assumption has implications for management (including catheter removal) and is discussed further later.[443]

Rapid diagnostic techniques have also been developed. The acridine-orange leukocyte cytospin test rapidly detects microorganisms in hub blood without catheter removal. It is nearly as sensitive as both the paired quantitative blood culture and differential time to positivity techniques.[566,571] Emerging molecular techniques include fluorescence in situ hybridization[358] and PCR,[692] although these methods are not routinely available in most clinical laboratories.

Empirical antimicrobial therapy for children with suspected bloodstream infection is similar to that for adults: the choice of therapy should be based on severity of illness, the nature and severity of underlying conditions, and the relative frequency and susceptibility patterns of local pathogens causing this infection. The clinical practice guideline cited previously contains detailed recommendations for management.[443] In most cases, empirical therapy should include coverage of both gram-positive and gram-negative bacteria. Owing to the increased prevalence of MRSA across institutions, vancomycin is now often included. Empirical combination therapy for multidrug-resistant gram-negative bacilli, such as *P. aeruginosa*, should be added for patients who are severely ill, neutropenic, or known to be colonized with such organisms. Empirical antifungal therapy may be considered in septic patients with risk factors for candidemia, including receipt of parenteral nutrition, prolonged use of broad-spectrum antibiotics, hematologic malignancy or receipt of bone marrow or solid-organ transplant, or known colonization with *Candida* spp. Unlike adult recommendations, empirical antifungal coverage is not recommended for children with femoral catheters when bloodstream infection is suspected.[443] Once culture information is available, treatment can be tailored or discontinued as appropriate.

There is substantial evidence that most uncomplicated bloodstream infections in children can be treated effectively without catheter removal.[216,443,711] However, catheter removal should be strongly considered with difficult-to-treat bacteria, such as *S. aureus*, *P. aeruginosa*, and mycobacteria.[443] In particular, treatment of catheter-associated fungemia without catheter removal has a relatively low success rate and may be associated with higher mortality.[165,444] Although a recent retrospective study among adults with catheter-associated candidemia found no difference in outcomes between early and late catheter removal, it did not address long-term outcomes such as recurrence.[490] This finding will require further consideration in future practice guidelines. Catheters should be removed immediately in patients with severe sepsis, embolic phenomena, septic thrombophlebitis, or endocarditis or if infection continues despite more than 72 hours of targeted therapy.

*References 304, 367, 455, 599, 636, 711, 718.

The bloodstream infection management guideline also reviews the use of antibiotic lock therapy in the treatment of catheter-related bacteremia when catheter salvage is the goal.[443] The concept behind lock therapy is that organisms embedded in biofilms on intraluminal surfaces of long-term catheters may be killed more effectively by antibiotic concentrations 100 to 1000 times higher than standard concentrations of therapeutic parenteral antibiotics.[443] Antibiotic lock solutions are typically mixed with heparin in sufficient volumes to fill the lumen, allowed to dwell, and then removed. This approach is currently recommended in conjunction with systemic therapy for select organisms. In particular, lock therapy is not recommended for infections due to *S. aureus* and *Candida* spp. unless unusual extenuating circumstances are identified.[443] Use of adjunctive urokinase or other thrombolytic agents is not recommended.[33,366,443]

Duration of therapy varies by pathogen type but is typically 7 to 14 days.[443] With catheter removal, shorter courses (i.e., 5 to 7 days) may be appropriate for uncomplicated infections with less virulent organisms such as coagulase-negative staphylococci. Persistently positive blood cultures despite targeted therapy or recrudescence of infection shortly thereafter should prompt catheter removal. Catheter removal from patients with persistent fever but no positive culture results and no evidence of infection elsewhere is controversial and should be approached on a case-by-case basis.

Some success has been reported in treating uncomplicated exit site infections with the catheter in place. A trial of combined local and systemic antimicrobial treatment is warranted before a decision to remove the catheter is made. In contrast, treatment outcomes of tunnel or pocket infections are generally poor if the catheter is retained.[443,711]

A guideline for the prevention of infections related to intravascular catheters has been published.[494] In addition, several reviews have focused on novel technologies in the prevention of these infections.[150,292,537] Key preventive measures are emphasized here and focus on aspects of insertion and maintenance.

In general, use of intravascular catheters and infusions should be limited to only when necessary. Reducing exposure to central venous catheters is one of the simplest ways to reduce the risk for bloodstream infections. Several reports have highlighted the significant impact of preventive measures during catheter insertion in reducing bloodstream infections in adults, often including "bundles" of practices.[53,534,691] These interventions include performance of hand hygiene and use of effective skin antiseptic (chlorhexidine-based agents are more effective than povidone-iodine or alcohol-based agents but are not approved by the U.S. Food and Drug Administration (FDA) for use in infants < 2 months of age)[124,150,237,421] in addition to maximal sterile barrier precautions (e.g., sterile gowns, gloves, and drapes).[538] The catheter site should be covered with either sterile gauze or a sterile, transparent semi-permeable dressing.[494] If sterile gauze dressing is applied, it must be removed or changed within 48 hours. Routine application of topical antimicrobial agents is not recommended.[150,494,495]

Ongoing preventive measures during catheter maintenance are also critical. A pediatric quality improvement collaborative revealed that maximizing compliance with insertion bundles was not sufficient to reduce bloodstream infection rates in pediatric ICUs, underscoring the importance of scrupulous practices related to routine catheter use and maintenance.[322,331,452,593,714] Many improvement initiatives over the past decade have advocated "bundling" of preventive practices—simultaneous implementation of multiple preventive practices to achieve maximal reductions in infections. These bundled preventive measures include adherence to aseptic technique during dressing changes as well as attention to dressing integrity. Several studies have evaluated the efficacy of chlorhexidine-impregnated sponge dressings, including a neonatal study.* In the largest, multicenter randomized clinical trial to date comparing chlorhexidine-impregnated sponges to standard dressings in adult ICU patients, rates of catheter-related infections were reduced even when background rates were low.[664] In the neonatal study, colonization rates were also reduced, but 15 percent of neonates weighing less than 1000 g developed contact dermatitis.[236] Current guidelines recommend chlorhexidine-impregnated sponges in patients aged older than 2 months if infection rates are high despite adherence to basic practices.[494] Daily bathing with 2 percent chlorhexidine cloths has also been shown to decrease rates of bloodstream infection in adult ICU patients.[186,461,472,529] Dedicated studies evaluating chlorhexidine bathing in pediatric ICU patients are pending.

The bloodstream infection prevention guideline also highlights the importance of minimizing catheter manipulation and provides detailed guidance around maintaining closed systems and when to change infusion sets.[494] Minimizing the frequency of catheter access is also a common preventive strategy at many hospitals, although there are few data to support this practice.

For patients with short-term devices, use of catheters impregnated with chlorhexidine/silver sulfadiazine (coating the external surface only) and minocycline/rifampin (coating both the internal and external surfaces) significantly reduces rates of bloodstream infection compared with use of uncoated catheters.[150,494,495,537] Although the majority of studies have been in adults, two nonrandomized studies of impregnated catheters in pediatric ICU patients suggested a decreased risk for infection.[62,126] In a head-to-head adult trial, minocycline/rifampin-impregnated catheters were associated with lower rates of infection than those impregnated with chlorhexidine/silver sulfadiazine.[164] Second-generation chlorhexidine/silver sulfadiazine–impregnated catheters (with higher levels of antiseptic and coating of both internal and external surfaces)[565] and minocycline/rifampin plus chlorhexidine–impregnated catheters have also been developed[539]; however, there are no published comparative studies using these catheters. The long-term impact of these catheters on antimicrobial resistance has not been evaluated, although prospective studies suggest that this risk is likely low.[494,580] In general, these catheters

*References 98, 236, 278, 390, 419, 664.

should be considered only after bundled standard procedures have been reliably implemented and infection rates remain elevated.

Multiple controlled studies have evaluated the use of antibiotic or antiseptic locks for the prevention of catheter-related bloodstream infections.[494] The majority of these studies have been performed in high-risk patient populations, including neonates and children with cancer or intestinal failure.[235,494,501] Multiple antibiotic lock solutions have been evaluated. A meta-analysis evaluating the use of antibiotic locks in hemodialysis patients found that antibiotic lock therapy significantly reduced catheter-related infections: they found that only four patients would need to be treated with lock therapy to prevent one infection.[720] Another recent meta-analysis compared the pooled effectiveness of ethanol with heparin locks in the reduction of bloodstream infection in children with chronic parenteral nutrition dependence and found that ethanol locks significantly reduced rates of both catheter-related infection and catheter replacement.[501] Current guidelines recommend prophylactic lock solutions in patients with long-term catheters with a history of multiple bloodstream infections despite maximal adherence to aseptic technique.[494]

Infections Related to Respiratory Therapy

Most infections related to respiratory therapy are associated with mechanical ventilation. Infections related to the use of other respiratory equipment, such as small-volume medication nebulizers, have also been described, but usually in the setting of an epidemic that was related to the use of contaminated equipment.[149,429,458] Here the discussion is focused primarily on ventilator-associated events or complications and conditions related to the use of mechanical ventilation. Major infections include tracheitis, tracheobronchitis, and pneumonia. In addition, mechanical ventilation may also increase the risk for sinusitis and otitis media in nasally intubated patients, because nasotracheal tubes interfere with normal drainage of the sinus ostia and eustachian tubes.[54,262] Of these syndromes, the vast majority of clinical and surveillance data exist for ventilator-associated pneumonia.

Among adults, ventilator-associated pneumonia has been reported in 9 to 27 percent of intubated patients and is associated with increased length of stay, hospital costs, and mortality.[496] Rates of ventilator-associated pneumonia among children in pediatric and neonatal ICUs are available from the CDC's NHSN report from 2010.[194] Ventilator-associated pneumonia comprised approximately 10 percent of all pediatric device-related infections reported to the NHSN; rates of pneumonia were generally lower in pediatric compared with adult ICUs. Similar to catheter-associated bloodstream infections, infection rates among neonates are inversely proportional to birth weight.[194] Aside from these reports of the rates of infection, dedicated studies of ventilator-associated pneumonia in infants and children are limited, although several reviews have summarized the existing pediatric literature.[218,532,682,717] The majority of information discussed below draws from studies in adults.

Most cases of ventilator-associated pneumonia are bacterial in origin and are polymicrobial. In general, the duration of mechanical ventilation prior to symptom onset is an important determinant of the most likely pathogens: "early" pneumonia (<4 days) is more likely due to antibiotic sensitive community pathogens, such as *S. pneumoniae* and *Haemophilus* spp., whereas "late" infections (>4 days) are more often related to antibiotic-resistant organisms.[22,309,494] This difference is thought to be related to the frequency of exposure to prior antimicrobial therapy as well as the local epidemiology of organisms prevalent in the ICU; the distinction may be less meaningful for patients who are frequently admitted to health care settings. Major pathogens include both gram-positive and gram-negative bacteria; *S. aureus* (including MRSA) and *P. aeruginosa* are isolated most frequently.[13,260,309] Other pathogens include *Streptococcus* spp., Enterobacteriaceae, and *Acinetobacter* spp.[242,309,554] Anaerobic bacteria are uncommonly implicated[309] but may play a role in polymicrobial infections, particularly when pneumonia is due to aspiration. Nosocomial viruses and fungi are rare causes of pneumonia in immunocompetent hosts. Although *Candida* spp. are isolated in some cases from samples obtained from the lower respiratory tract, they rarely, if ever, are the primary cause of pneumonia.[22]

Ventilator-associated pneumonia occurs when bacteria invade the pulmonary parenchyma of a patient receiving mechanical ventilation.[139] This process is directly linked to aspiration of oropharyngeal or gastric secretions that harbor potentially pathogenic organisms.[22,309] Colonization with pathogenic bacteria is facilitated by a number of factors, including enhanced bacterial adherence to mucosal surfaces in severely ill or debilitated patients, bacterial overgrowth of the stomach when acid-suppressing medications are used, as well as reductions in microbial diversity and pathogen selection due to antibiotic exposure.[496,647] The presence of an endotracheal tube also interferes with normal protective airway reflexes and prevents effective coughing. Subsequently, contaminated secretions pool and leak around the endotracheal tube; this process is exacerbated during changes in position or deflation of the subglottic cuff of the endotracheal tube cuff. Bacterial biofilms also form on the inner surface of the tube, providing a direct route for microbial invasion into the lower airway.[496]

Regurgitation of bacteria from the stomach into the pharynx may provide another route for bacteria into the airway; normal gastric pH prevents heavy contamination of stomach contents, but bacteria proliferate when stomach acid is neutralized by antacids or histamine-2 (H_2) blockers. Still, the degree to which gastric colonization contributes to risk for pneumonia is unclear.[647] Other potential pathways for infection include use of contaminated equipment or medications, often in outbreak settings,[405] and bacteremia with hematogenous spread.[22]

Once pathogens enter the lower airway, host defenses are important in determining whether infection results. Diseases that compromise mucociliary clearance or the ability of the immune system to contain and inactivate pathogens dramatically increase the risk for infection.

Risk factors for ventilator-associated pneumonia in adults can be classified into several categories: (1) host factors that increase susceptibility to pneumonia, such as advanced age, underlying chronic lung disease, and immunosuppression; (2) treatment factors that enhance colonization of the oropharynx or stomach with pathogenic bacteria, including administration of antimicrobials or agents that increase gastric pH; (3) factors that promote reflux of gastric contents and aspiration into the lower airway, such as depressed mental status, supine positioning, nasogastric tubes, and enteral feeding; (4) conditions that increase duration of ventilation; and (5) factors that hinder adequate pulmonary toilet, such as thoracic or abdominal surgery and immobilization.[647]

Although dedicated pediatric studies are limited, it is likely that many of these adult risk factors are also important in children. Prospective studies of critically ill children have found that the presence of a genetic syndrome, postsurgical admission diagnosis, prior antibiotic therapy, use of narcotic medications, presence of enteral feeds, reintubation, and transport out of the ICU were independently associated with ventilator-associated pneumonia.[13,203,633] Trauma,[648] female gender,[633] and gastroesophageal reflux disease[2] have also been associated with ventilator-associated pneumonia in children in single studies.

The diagnosis of ventilator-associated pneumonia can be challenging. Clinical diagnosis requires evaluation of a combination of clinical, radiographic, and microbiologic data. Relevant clinical findings include fever, leukocytosis or leukopenia, purulent secretions, and worsening gas exchange. Auscultation is often hindered by sounds of the ventilation system itself (particularly with high-frequency ventilation); in addition, a variety of underlying pulmonary diseases and conditions (e.g., fluid overload) may produce sounds indistinguishable from those present in pneumonia. Radiographic findings include new or progressive pulmonary infiltrates, cavitation, air bronchograms, or pneumatoceles. Air bronchograms are the most sensitive for pneumonia[682]; however, chest radiograph findings have only limited specificity, because significant overlap exists between pneumonia and other pulmonary conditions.

Microbiologic data are important both in diagnosis and in guiding subsequent treatment. Samples of lower respiratory tract secretions should be obtained on all patients with suspected ventilator-associated pneumonia in addition to blood cultures. A variety of invasive and noninvasive methods have been evaluated in obtaining respiratory specimens, although the optimal diagnostic method remains unclear.[88,606,661] A recent meta-analysis found no difference in quantitative versus qualitative respiratory cultures (nor in invasive vs. noninvasive techniques) in reducing mortality, time in ICU or on mechanical ventilation, or rates of antibiotic change in adult patients with ventilator-associated pneumonia.[58] Lung biopsy and bronchoscopic bronchoalveolar lavage are the gold standards for diagnosis but are not routinely used in immunocompetent children. Tracheal aspirates are obtained most commonly but may be misleading in an asymptomatic patient, because endotracheal tubes are often colonized with potential pathogens.[251] Gram stains are helpful in ruling out pneumonia when negative but have very poor positive predictive value,[497] because localized irritation or superficial infection of the trachea may produce purulent secretions.

Significant controversy exists around surveillance definitions; as of 2012, NHSN[300] and the American Thoracic Society/Infectious Diseases Society of America (IDSA)[22] definitions have differing timelines to meet criteria, making institutional comparisons difficult. A streamlined definition for ventilator-associated pneumonia has been evaluated that has produced rapid and reliable results with similar ability to predict patient outcomes.[349] The CDC plans to issue a revised definition for adults older than 18 years in January 2013 that will include any ventilator-associated event (not limited to pneumonia), require a minimum period of time on the ventilator, focus on objective clinical data, and does not include radiographic findings.

Empirical therapy for ventilator-associated pneumonia should be based on the duration of intubation and hospitalization, prior or current antibiotic therapy, severity of clinical disease (as well as the nature and severity of underlying conditions), and knowledge of the relative frequency and susceptibility patterns of local pathogens. Several adult studies have shown that delayed initiation or inappropriate antibiotic therapy is associated with poor outcomes.[22] Initial broad-spectrum therapy with adequate coverage of gram-negative bacilli, including *P. aeruginosa*, and possibly MRSA as guided by local epidemiology, is generally appropriate and may be narrowed based on subsequent culture data and clinical and radiographic findings.[22]

Prolonged treatment of patients in whom the diagnosis is questionable should be avoided because this practice may lead to endotracheal colonization with antimicrobial resistant bacteria. Treatment duration for ventilator-associated pneumonia has not been evaluated in children. As in adults, uncomplicated cases may be treated with 7 to 10 days of therapy. For complicated cases, or those with necrotizing pneumonia, at least 14 days of therapy should be administered. Shorter courses (<7 days) may be appropriate for children with ventilator-associated tracheitis without evidence of pneumonia.[655] Nasotracheally intubated patients with otitis media or sinusitis should have the nasotracheal tube changed to an orotracheal tube. Short-term treatment with a decongestant and sinus lavage may also be beneficial in sinusitis treatment.

Comprehensive guidelines for prevention of health care–associated[647] and ventilator-associated pneumonia[139] are available. Key strategies include three major themes: (1) reducing aspiration of secretions, (2) reducing colonization of the aerodigestive tract, and (3) preventing use of contaminated equipment.[139] Many strategies are implemented as practice "bundles," aimed at producing more robust results when combined.[65,157,496]

General strategies for prevention include limiting the duration of ventilation and using noninvasive approaches whenever possible. Daily assessment of readiness to wean and the use of weaning protocols may also be effective, in conjunction with daily interruption of sedation.[139,665] Although a randomized clinical trial among ventilated

children failed to demonstrate a reduction in time to extubation with the use of a volume support weaning protocol, the majority of children included in the study were weaned from ventilator support in less than 2 days.[544] Hand hygiene and use of gloves during contact with objects or surfaces contaminated with respiratory secretions are also important.

Aspiration can be minimized by maintaining patients in a semirecumbent position with elevation of the head of the bed to 45 degrees, although this position may be difficult to achieve consistently.[139] Novel approaches to positioning have gained recent attention. A clinical trial involving 60 intubated infants found that lateral positioning (keeping the tube at or below the horizontal plane) was associated with a significantly decreased frequency of positive tracheal cultures compared with patients who were supine.[15] Additional, larger randomized studies in adults are underway.[496]

Keeping the endotracheal tube free of secretions is also important in preventing aspiration. Use of a cuffed endotracheal tube with subglottic or in-line suctioning is recommended in adults; however, cuffed tubes are not used routinely in all children, especially infants, and in-line suctioning has not been studied in children. Subglottic suctioning has been evaluated in a recent meta-analysis of adult patients and found to reduce significantly the incidence of ventilator-associated pneumonia.[689] Suctioning should be performed by gently using a sterile, single-use catheter, and sterile fluids should be used to loosen secretions and clear the suction catheter. A novel approach to removing secretions from the interior lumen of the endotracheal tube (called the mucus shaver) has been evaluated in a small randomized clinical trial in adults and found to significantly reduce colonization of the tube.[56] If this finding is reproduced in larger studies, this device may enhance our ability to keep endotracheal tubes free from secretions and heavily colonized biofilms.[496] Other measures to reduce aspiration include avoiding unplanned extubation and reintubation and avoiding gastric overdistention.

Strategies to reduce colonization of the aerodigestive tract include regular oral care with antiseptics. In particular, a recent meta-analysis showed that use of an oral chlorhexidine rinse significantly reduces rates of ventilator-associated pneumonia in adults.[368] Avoiding acid suppression in patients who are not at high risk for developing stress ulcers or gastritis is another strategy but has yielded inconsistent results.[139,647] In particular, a retrospective study of ventilated children found that a strategy used to prevent gastrointestinal bleeding was not associated with risk for ventilator-associated pneumonia.[402]

Prophylactic antibiotic regimens have also been used to modulate oropharyngeal colonization.[139,647] Specifically, selective decontamination of the digestive tract uses a combination of nonabsorbable oral antimicrobial agents, systemic cephalosporins, and avoidance of antibiotics with anti-anaerobic activity to prevent secondary bacterial colonization, preemptively treat possible respiratory tract infection with commensal organisms, and preserve normal intestinal microbiota, respectively.[174] Selective oropharyngeal decontamination is similar but includes application of topical oropharyngeal antimicrobial agents only. Selective decontamination of the digestive tract[172,174,359,613] has been shown to reduce mortality among adult ICU patients in randomized clinical trials, including a systematic review, but is not recommended routinely owing to increased selective pressure on antibiotic-resistant organisms in areas with high levels of endemic multiple-drug resistance.[139,647]

To minimize contamination of respiratory equipment, sterile water should be used to rinse reusable devices. Tubing should be maintained in a dependent position relative to the endotracheal tube, and condensate should be routinely discarded; circuits should remain closed during condensate removal. The ventilatory circuit should be changed only when visibly soiled or malfunctioning. All respiratory equipment should be stored and disinfected properly.[139] Items with direct or indirect contact with mucous membranes or respiratory secretions should be cleaned thoroughly and either sterilized or disinfected in a manner consistent with high-level disinfection.

Infections Related to Instrumentation of the Urinary Tract

Urinary tract infections are the most common health care–associated infections in hospitalized adults worldwide.[299] In fact, catheter-associated urinary tract infections accounted for approximately 40 percent of all device-related infections reported to the NHSN in 2010.[194] In contrast, catheter-associated urinary tract infections are a much smaller proportion (approximately 12%) of device-related health care–associated infections in hospitalized children.[194,219,319,373,704] This difference is largely explained by differences in urinary tract catheterization between adults and children. Still, the infectious risk associated with the use of indwelling urinary catheters is similar in adults and children; pooled means of catheter-associated urinary tract infections are similar between adult and pediatric units reporting to the CDC's NHSN in 2010.[194]

Although diagnostic criteria for catheter-associated urinary tract infection vary, and are often reported differently between studies, surveillance definitions have been established.[300] Urinary tract infections are catheter associated if the patient had an indwelling catheter in place at the time of or within 48 hours of onset. Symptomatic urinary tract infection is defined as the presence of signs or symptoms of infection (e.g., fever, urgency, frequency, dysuria, or suprapubic tenderness) and a quantitative urine culture with 10^5 or more colony-forming units (CFU) per milliliter of no more than two different species.[300] Lower colony counts ($\geq 10^3$ CFU/mL) are accepted with evidence of pyuria and organisms on Gram stain in a symptomatic patient. Asymptomatic bacteriuria or candiduria is defined as the presence of a quantitative urine culture with 10^5 CFU/mL or more of no more than two different species in a patient without signs or symptoms referable to the urinary tract.[299]

Urinary tract infections in patients with short-term indwelling catheters (<30 days) are usually caused by single organisms while infections in patients with

long-term catheters (>30 days) are more often polymicrobial.[299] *E. coli* is the most frequently isolated species in both children and adults but comprises less than one third of isolates.[2,299,502] Other gram-negative bacteria, including Enterobacteriaceae and *P. aeruginosa*, and *Enterococcus* spp. and various *Candida* spp. are also isolated.* In a single-center pediatric study, recent antibiotic exposure within the prior 2 months was more common in children with infections with *P. aeruginosa* as compared with children with infection due to *E. coli*.[67] The percentage of urinary tract infections attributed to coagulase-negative staphylococci has been reported in excess of 30 percent in neonatal ICU patients.[168,398]

Microbial colonization of the urine is the first step in the pathogenesis of urinary tract infection; the urinary catheter facilitates this by perturbing host defenses and providing uropathogens easier access into the bladder. Still, infection is not an inevitable result of bladder colonization, and many chronically catheterized patients may have evidence of urine colonization for long periods without clinical evidence of infection. Pathogens may be introduced at catheter insertion, by ascension along the external catheter surface, or intraluminally through contamination of the collecting tube or drainage bag. A detailed culturing study of catheterized patients suggests that roughly two thirds of infections are caused by extraluminal spread of microorganisms along the external catheter surface while the other one third are intraluminally acquired.[651] Additional support for the extraluminal route comes from a number of studies in catheterized adults correlating microorganisms colonizing the urethral meatus with those most frequently causing infection.[91]

After catheter insertion, adherence of microbes along the internal and external surfaces of the catheter leads to colonization and facilitates the rapid formation of biofilms composed of host proteins and microbial exopolysaccharides. These biofilms become polymicrobic and migrate to the bladder within 1 to 3 days.[299,316,576] Movement of microorganisms into the bladder is facilitated by obstruction of urine flow and reflux of urine into the bladder (i.e., raising the collection system above the level of the bladder), but many bacteria can migrate upstream even in properly maintained systems. Catheter encrustations may be formed by urease-splitting organisms within biofilms, such as *Proteus* and *Providencia* spp., serving as additional sites for microbial proliferation and attachment.[299] Once introduced in the bladder, microorganisms multiply in the small, but persistent, reservoir of urine that is incompletely drained by the catheter.[91]

The incidence of catheter-associated bacteriuria is reported between 3 and 8 percent per day; duration of catheterization is the most important risk factor.[299] Other risk factors for catheter-associated bacteriuria identified in adults include female sex, catheter insertion outside the operating room, catheter care violations, older age, and rapidly fatal underlying illness.[299] The epidemiology of bacteriuria and urinary tract infections has also been evaluated in children, although most studies are dated.† In a large prospective study of 525 hospitalized children with urinary catheters, bacteriuria was identified in 11 percent of all catheterized patients, of which 78 percent were symptomatic; median duration of catheterization preceding bacteriuria was 7 days (range, 2 to 77 days).[399]

There are no published data regarding rates of urinary tract infection associated with different types of indwelling catheters (e.g., urethral, suprapubic, ureteral, nephrostomy) in children, although anecdotal evidence suggests that bacteriuria and candiduria are more common in catheters that remain in place for long periods regardless of catheter type. Bacterial colonization of urinary stents is common in children, although its clinical significance remains unclear.[51,672] Urinary tract infections are also very common after renal transplantation, occurring in up to 40 percent of children.[205,210,612,680] Age younger than 5 years, lower urinary tract abnormality, and prior history of urinary tract infection or vesicoureteral reflux before transplant have been associated with increased infection risk in these children.[205,210] Data regarding the incidence of infection after other types of urinary tract instrumentation in children are not available.

The diagnosis of symptomatic catheter-associated urinary tract infection is often challenging because many catheterized patients do not manifest symptoms such as urgency, frequency, or dysuria. Consequently, fever is the most commonly identified sign of infection in these patients, emphasizing the importance of a quantitative urine culture in the evaluation of a new fever in a catheterized child. Pyuria is a reasonably good predictor of the presence of significant concentrations of gram-negative rods in the urine of catheterized patients but is a poor predictor for the presence of significant concentrations of enterococci or *Candida*.[652] Still, the presence of pyuria alone is not diagnostic for infection in a catheterized patient, particularly those with long-term indwelling catheters.[299] Conversely, the absence of pyuria in a symptomatic catheterized patient suggests an alternative diagnosis.

Definitive diagnosis of catheter-associated urinary tract infections depends heavily on quantitative urine culture results (see earlier discussion). In patients with short-term catheters, specimens should be collected from the aspiration port using aseptic technique. With long-term catheters, removing the catheter and collecting a specimen from a freshly placed catheter before initiating therapy is preferred.[299] Specimens should not be collected from the drainage bag.

Empirical antimicrobial therapy for urinary tract infection should be based on the severity of clinical disease, the nature and severity of underlying conditions, and knowledge of the relative frequency and susceptibility patterns of local pathogens. Parenteral therapy is typically used until excluding secondary bacteremia. Therapy with a broad-spectrum agent targeting gram-negative bacilli, potentially including *P. aeruginosa*, and enterococci is generally appropriate. Antifungal therapy can usually be withheld, unless yeast elements are identified on urinalysis or urine Gram stain. Based on the patient's clinical status and culture results, the treatment regimen can be tailored accordingly or discontinued.

*References 2, 168, 299, 398, 399, 502.
†References 63, 67, 168, 373, 398, 399, 502.

Seven days of antimicrobial therapy is generally recommended for treatment of most catheter-associated urinary tract infections; longer courses (10 to 14 days) are used for those with a delayed response or with evidence of pyelonephritis.[299] If the infection is uncomplicated and the child has responded clinically, oral therapy can be used to complete the course. Whenever possible, indwelling urinary catheters should be removed. Infections involving nephrostomy or suprapubic catheters often recur if these catheters must remain in place. In cases in which nephrostomy tubes must be used for extended periods, suppressive antimicrobial therapy may be considered after treatment is completed, although there is a risk for secondary infection with resistant bacteria or yeast with this approach.

Guidelines for the prevention of catheter-associated urinary tract infections have been published and the key features are summarized here.[256,299] Reducing unnecessary use of urinary catheters, including leaving them in place only as long as needed, is the most important and effective preventative measure. Simple interventions, including nurse-based or electronic physician reminder systems to reduce inappropriate catheterization, have been shown to reduce significantly the rates of catheter-associated urinary tract infections in both children and adults.[87,168,441]

Urinary catheters should be inserted by trained personnel using aseptic technique. After insertion, contamination of the interior surfaces of the catheter and collection system can be minimized by maintaining a closed system (i.e., avoiding disruption of the connection between the catheter and the collection system) and ensuring that the drainage bag and connection tube are kept below the level of the bladder. Antimicrobial (silver alloy or antibiotic)-coated catheters have been shown to reduce or delay the onset of catheter-associated bacteriuria in adult patients with short-term catheters, but it remains unclear whether the use of these catheters reduces the incidence of symptomatic infection, particularly in patients with long-term catheters.[299] There have been no studies of novel urinary catheters in children.

Although systemic antibiotics have been shown to reduce or delay the onset of catheter-associated bacteriuria or infection in many adult studies,[91] their use at the time of catheter insertion, removal, or replacement is not routinely recommended, owing to the potential for adverse effects and the development of antimicrobial resistance.[299] A wide variety of other interventions have been studied, primarily in adults and most with limited or variable benefit.[91,299,422] At present, the routine use of methenamine salts or cranberry products is not recommended for the prevention of catheter-associated urinary tract infections.

Infections Related to Surgical Procedures

Patients undergoing surgical procedures are at risk for a variety of health care–associated infections, including bacteremia, pneumonia, and urinary tract infection (often related to the presence of other medical devices), but surgical site infections are most common.[61,528] A number of reports describing the epidemiology of surgical site infections in general pediatric surgery patients have been published, although most are dated.* More recent analyses of large cohorts of pediatric surgical patients have shown rates of surgical site infections between 1.3 and 6.6 percent after surgery.[468,548,671] Surgical site infections have a significant impact on patient outcomes, including increased duration of hospitalization, health care costs, and increased risk for death.[24]

Consensus criteria for surgical site infections are available from the CDC's NHSN.[300] Surgical site infections are subcategorized into either incisional (superficial or deep) or organ/space infections and are summarized in Table 243-7. Surveillance definitions require that infections arise within 30 days of surgery, unless an implant is left in place, in which case infections may be identified for up to 1 year. Implants are defined as non–human-derived objects (e.g., prosthetic valves) that are permanently placed and not routinely manipulated for diagnostic or therapeutic purposes.[300] Stitch abscesses are not considered surgical site infections.

Traditionally, the NHSN has provided simple risk adjustment measures to account for differences in case mix and allow for meaningful comparisons between surgeons or hospitals. Previously, three equally weighted factors were included: (1) composite measure of severity of illness (the American Society of Anesthesiology [ASA] score); (2) wound classification I to IV (e.g., clean, clean-contaminated, contaminated, and dirty-infected); and (3) procedure duration.[154] Recently, the NHSN has developed procedure-specific risk models for each procedure category reported to the NHSN, which incorporate existing patient and hospital-specific data elements. These models have been shown to improve predictive performance compared with traditional risk stratification and are intended to facilitate improved external benchmarking.[467]

Among pediatric studies, independent risk factors for infection include longer surgery duration[61,167,169,190]; younger age[90,190,414,600]; nonwhite race[90]; prolonged preoperative hospitalization[167,169,190]; emergency surgery[60,190,666]; longer length of incision[167,190]; procedure performed by a trainee[666]; and presence of underlying diseases.[60] Potentially modifiable risk factors identified in a recent study included postoperative ICU admission, urinary catheter placement, and use of an implantable device.[90]

Additional data exist for specific surgery types. In particular, children undergoing cardiovascular surgery are at high risk for infection owing to the complexity of congenital heart disease and the aggressive medical management required to support them through recovery. A prospective study of over 300 children undergoing cardiovascular surgery found an infection rate of 7.1 percent; infection rates were higher among patients with an open sternotomy after surgery and among those with increased severity of illness (i.e., higher Pediatric Risk of Mortality [PRISM] score).[528] Subsequent studies have identified prolonged duration of surgery,[12,330,476] younger age[12,50,330,476] (specifically, age <30 days[629]), cyanotic heart

TABLE 243-7 National Healthcare Safety Network Surveillance Definitions for Surgical Site Infections (SSI)*

Incisional SSI†

Superficial: Infection involves skin or subcutaneous tissue of the incision *and* patient has at least *one* of the following:
- Purulent drainage from superficial incision
- Organisms isolated from an aseptically obtained culture of fluid or tissue from superficial incision
- At least *one* sign or symptom of infection (pain/tenderness, localized swelling, redness or heat) *plus* superficial incision is deliberately opened by surgeon *and* is either culture positive or not cultured
- Diagnosis of superficial incisional SSI by surgeon or attending physician

Deep: Infection involves deep soft tissues (e.g., fascial, muscle layers) of the incision *and* patient has at least *one* of the following:
- Purulent drainage from the deep incision (excluding organ/space component)
- Deep incision spontaneously dehisces or is deliberately opened by a surgeon *and* is culture positive or not cultured *and* patient has at least one sign or symptom (fever >38° C, localized pain/tenderness)
- Abscess or other evidence of infection involving deep incision found on direct examination, reoperation, or by histopathology for radiologic examination
- Diagnosis of deep incisional SSI by surgeon or attending physician

Organ/Space SSI

Infection involves any part of the body (excluding the skin incision, fascia, or muscle layers) that is opened or manipulated during the operative procedure *and* patient has at least *one* of the following:
- Purulent drainage from a drain that is placed through a stab wound into the organ/space
- Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
- Abscess or other evidence of infection involving organ/space found on direct examination, reoperation or by histopathology for radiologic examination
- Diagnosis of organ/space SSI by surgeon or attending physician

*For all classifications, infection is defined as occurring within 30 days of the operative procedure if no implant in place or within 1 year if an implant is in place and the infection is related to the procedure.

†Incisional infections may be primary (related to the primary incision made by the surgeon) or secondary (related to a secondary incision, e.g., donor site for coronary artery bypass graft).

See the NHSN website for the latest updates in NHSN definitions and methodology (www.cdc.gov/nhsn).

Modified from Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of health care–associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;**36**:309-32.

disease,[50] undergoing more than one cardiothoracic procedure,[297] having a preoperative medical device,[629] and parenteral nutrition as independent risk factors.[629]

Infection rates after cerebrospinal fluid shunting procedures vary widely.[372,499] A recent analysis of shunt infection rates across 41 free-standing children's hospitals reported infections in more than 11 percent of patients undergoing shunt procedures over a 24-month period, with adjusted hospital level rates between 1.4 and 5.3 percent per procedure.[616] Shunt infections rates are higher among those with perioperative cerebrospinal fluid leak,[321] history of prior shunting procedure,[499] and myelomeningocele.[499] Additional risk factors include younger age and shunt revision.[617]

Surgical site infections are also common in orthopedic patients, particularly after revision surgery, posterior spinal fusion, or the placement of implants.[621] A recent study evaluating rates of infection after posterior spinal fusion at a tertiary care children's hospital reported mean annual infection rates of 4.4 percent.[393] An ASA score greater than 2, obesity, and antibiotic prophylaxis with clindamycin were independent risk factors for infection; of note, the majority of pathogens isolated were gram-negative bacilli.

The most recent national surveillance data on the microbiology of surgical site infections among children in pediatric ICUs identified gram-positive cocci in nearly half of all isolates[554]; *S. aureus* was the most common, but coagulase-negative staphylococci and *Enterococcus* spp. were isolated frequently. Gram-negative bacilli comprised 40 percent of isolates. Anaerobes, including *Bacteroides fragilis*, are uncommonly isolated, but anaerobic cultures may be infrequently performed. *Candida* spp. are isolated from a minority (4%) of patients. This distribution of microorganisms is similar to findings from several studies of surgical site infections in general pediatric and cardiovascular surgery patients*; however, a recent retrospective study of surgical site infections at a pediatric tertiary care center reported that 21 percent of culture-positive infections were polymicrobial.[90] Gram-positive bacteria are more commonly isolated in cerebrospinal fluid shunt infections[499,670]; *Propionibacterium acnes* is among those isolated but typically produces milder symptoms and requires longer incubation times for isolation.[31]

The pathogenesis of surgical site infection involves a complex relationship between microbial characteristics, host factors, and the nature of the surgical procedure. The greatest risk for microbial contamination of the surgical site occurs while the wound is open. If the incision is closed primarily, subsequent contamination from external sources is uncommon. The vast majority of contamination arises from endogenous flora at or near the surgical site, including microorganisms colonizing the skin, mucous membranes, and hollow viscera.[425] Postoperative hematogenous seeding from endogenous flora at remote sites can occur but is uncommon. Exogenous contamination from colonized or infected surgical personnel, surgical instruments, or the operating room environment are infrequently implicated as causes of infection.[36,255,557] Unusual environmental pathogens, including airborne fungal spores, are occasionally implicated.[555]

Even with careful skin preparation and expert technique, microbial contamination is virtually universal. Although skin organisms are a common cause of infection, a significant number of these organisms reside in skin appendages, such as sebaceous glands and hair

*References 61, 90, 167, 198, 528, 600.

follicles, which are not exposed to topical antiseptics.[425] Thus, careful surgical technique is required to avoid conditions that favor microbial growth postoperatively. These conditions include damaged or devascularized tissue resulting from rough handling or overuse of electrocautery, as well as hematomas and seromas, which provide optimal bacterial growth conditions. Burden of inoculation is also critical, and required inoculums for infection may be lower in the presence of foreign bodies or material.[24]

Surgical site infections rarely occur within 48 hours of surgery, except in cases of infection with *S. pyogenes* or *Clostridium* spp.; therefore, fever within 48 hours of surgery is unlikely to be related to the surgical site.[637] Once identified, management of surgical site infections may require a combination of surgical débridement and antimicrobial therapy, depending on the location and extent of infection. Superficial incisional infections may be treated topically or with oral antibiotics alone, whereas deep incisional and organ/space infections almost universally require débridement and drainage; contemporary interventional radiology techniques have revolutionized this process. In some cases, fluid collections may be inaccessible or attempts at drainage may compromise the patient's condition. In these cases, antibiotics may be tried alone, although therapy should be chosen carefully and clinical response monitored closely.

The presence of prosthetic or foreign material complicates management. In particular, shunt infections are unlikely to resolve without shunt removal.[721] In some special cases, antimicrobial therapy can successfully suppress infection with foreign material while postoperative healing takes place (i.e., plates and screws to stabilize bones after orthopedic procedures). However, device removal is typically recommended to achieve cure. The likelihood of salvage of an infected prosthesis improves if the infection is detected within 3 weeks of implantation, the implant remains stable and the surrounding tissue is healthy, and the patient receives appropriate systemic antimicrobial therapy.[725] With prosthetic joint infections, most patients receive 6 to 8 weeks of intravenous antimicrobial therapy.[725]

Guidelines for the prevention of surgical site infections are available[81,425] and have been recently updated.[11] Similar to efforts targeting other device-related infections, many of these practices have been "bundled" to reduce surgical site infections in many hospitals with good success.[568] Key preventive measures aimed at minimizing microbial contamination of the surgical site are summarized next.

Preoperative interventions can impact both the nature and degree of microbial contamination. In general, minimizing preoperative hospitalization can prevent colonization with hospital-acquired pathogens. In addition, identifying and treating preexisting infections at remote sites is recommended. The use of preoperative bathing to reduce the number of bacteria colonizing the skin before surgery is widespread, although its effect on reducing infection is unclear. Preoperative showering with chlorhexidine has been shown to reduce the number of bacteria at the incision site better than povidone-iodine or soap and water[11,425]; in addition, preoperative chlorhexidine shampoo was found to be superior to iodophor products in reducing the number of scalp microorganisms prior to neurosurgical procedures in children.[380] More substantial reduction of bacteria is seen with multiple showers or with showers immediately preceding surgery, suggesting that timing may be important.[11] Still, there is no definitive evidence that this practice reduces rates of infection.[11,425] A meta-analysis evaluating the effect of preoperative chlorhexidine bathing compared with other wash products found no clear benefit in reducing infection risk.[698]

The preoperative use of intranasal mupirocin to reduce infections has also been studied. The largest study to date was a randomized controlled trial among adult surgical patients undergoing a variety of procedures.[520] Although intranasal mupirocin was not associated with a reduction in surgical site infections compared with placebo, it significantly reduced the rate of all nosocomial *S. aureus* infections among patients who were *S. aureus* nasal carriers. A dedicated meta-analysis evaluating the effect of intranasal mupirocin in reducing *S. aureus* infections in surgical patients with nasal carriage also found a significant reduction in all *S. aureus* infections postoperatively; however, their results were heavily influenced by the large study cited previously.[679] Mupirocin resistance was infrequently reported among the studies included in the meta-analysis but has been reported after widespread use of nasal mupirocin in other studies.[451] Screening of patients for colonization is not universally recommended but may be considered in high-risk groups, such as those undergoing placement of prosthetic devices in regions where the community prevalence of MRSA is high.

Although removing hair appears to provide a "cleaner" operative site, current evidence suggests that shaving is associated with higher rates of infection, presumably owing to microscopic skin trauma and liberation of resident skin flora from deep skin structures.[11] If hair removal is necessary, current evidence suggests that clippers should be used over razors.[657] If required, most recommend hair removal immediately before surgery; however, a meta-analysis found no difference in infection rates between hair removal one day before or the day of surgery[657]; however, the authors note that studies were small and more research is needed.

Perioperatively, the use of antimicrobial prophylaxis is among the most important measures to prevent infection.[11] Numerous studies have examined the effectiveness of antimicrobial prophylaxis, although few have included children. A comprehensive "meta-analysis of meta-analyses" included 250 clinical trials with over 4800 patients to determine whether antibiotic prophylaxis is effective in preventing surgical site infections across a variety of procedures and found that perioperative antibiotics significantly reduced infection risk across 23 surgery types evaluated.[74] In addition, the protective effect was sustained across different levels of surgery cleanliness.[74] The most effective time for antibiotic administration is within 30 minutes of skin incision, except for agents such as vancomycin that require longer infusion times and therefore should be administered between 1 and 2 hours before surgery.[11] If prophylaxis is given outside this period, effectiveness is diminished and

has virtually no effect more than 6 hours after the incision.[136] If surgery is prolonged, re-dosing should be performed after two half-lives of the administered agent have elapsed. Antimicrobial agents should be stopped within 24 hours after the procedure.

A variety of intraoperative practices and procedures are used to prevent contamination of the surgical site, including use of antiseptics such as alcohols, iodophors, and chlorhexidine.[425] The surgical hand scrub by surgical personnel reduces the number of bacteria on the hands and the potential for contamination through visible or microscopic breaks in surgical gloves. A systematic review found that alcohol rub was as effective as aqueous scrubbing; however, meta-analysis was precluded by major differences between studies.[658] Skin antisepsis also reduces the number of viable bacteria at the surgical site. Current evidence from randomized clinical trials and meta-analyses suggests that use of chlorhexidine is superior to that of iodophors in preventing surgical site infections and results in cost savings.[163,382] However, a follow-up observational study evaluating use of povidone-iodine for disinfection found that residual bacteria left behind at the incision site were not associated with increased risk for infection.[669] Barrier precautions, including masks, caps, and gowns, are a major part of practice and provide protection for surgical personnel against blood and body fluid exposures, although their impact on infection risk is unclear. Operating room traffic should also be minimized, because activity increases bacterial counts in the air; however, the effect on infection risk is likely small. Bacterial counts can also be minimized by regularly servicing operating room ventilation systems and maintaining adequate ventilation parameters.[21]

Proper surgical technique is critical in preventing infection and cannot be overridden by any other measure.[11] Closed-suction drainage systems are frequently used in orthopedic surgeries to drain fluids from the surgical wound and reduce occurrence of hematoma; however, there is insufficient evidence from randomized trials to routinely recommend this practice.[512] A number of studies have demonstrated that confidential feedback of surgeon-specific rates of infection to individual surgeons allows them to adjust their practices accordingly and reduces overall infection rates.[662]

Other interventions evaluated in adult patients include glycemic control, maintenance of normothermia, and supplemental oxygen. These measures have not been investigated in pediatric surgical patients. In particular, tight glycemic control may have untoward consequences in special populations of children, particularly infants, and is in need of further study.

HEALTH CARE–ASSOCIATED INFECTIONS CAUSED BY SPECIAL PATHOGENS

Methicillin-Resistant *Staphylococcus aureus*

Methicillin-resistant *S. aureus* (MRSA) has long been recognized as a nosocomial pathogen and accounted for over 50 percent of *S. aureus* health care–associated infections in adult patients reported to the CDC in the 1990s.[477] In contrast, point prevalence surveys performed in the late 1990s by the Pediatric Prevention Network documented that only 2 percent of pediatric health care–associated infections were due to MRSA.[260,628] The emergence of novel strains of MRSA associated with community-onset infections has changed the epidemiology of health care–associated MRSA infections. The prevalence of MRSA in pediatric health care–associated infections has risen dramatically; over one fourth of all *S. aureus* infections in neonatal ICUs are due to methicillin-resistant strains.[385] Evidence from multiple adult and pediatric studies has demonstrated that community-associated MRSA strains (as defined by the unique mobile genetic element, the SCC*mec*IV cassette) have now become endemic in many institutions.[329,428]

This changing epidemiology has had an unfortunate impact on patients. As compared with patients with health care–associated infections due to methicillin-sensitive strains of *S. aureus*, patients with similar infections due to MRSA often have worse outcomes with increased rates of death, longer durations of hospitalization, and higher total hospital costs.[144,145,204] Risk factors for MRSA health care–associated infections include colonization pressure (the proportion of patients with MRSA carriage) within a given unit or institution, exposure to broad-spectrum antibiotics, prolonged hospital stay, and use of indwelling medical devices.

Prevention of health care–associated MRSA infections has been the topic of several recent guidelines from experts in the fields of infectious diseases and hospital epidemiology.[96,314,473,609] Key prevention principles rest on (1) identifying reservoirs of the organism; (2) strict adherence to hand hygiene to interrupt transmission via transient carriage on the hands of caregivers and visitors; (3) cohorting to prevent contamination of the environment of a noncolonized patient; (4) decontaminating the patient care environment and using dedicated patient equipment; and (5) antimicrobial stewardship.[96]

Over the past decade, several areas of controversy have emerged in the discussion of how to prevent MRSA health care–associated infections. A large cluster-randomized trial performed in adult ICUs, the STAR*ICU trial, examined the impact of active surveillance cultures (MRSA screening by culture or PCR of specimens obtained by nasal swabs from all newly admitted patients) and expanded barrier precautions (contact precautions for MRSA colonized or infected patients and universal gloving for all other patients).[311] In this study, active surveillance for MRSA and barrier precautions did not reduce the incidence of MRSA acquisition, although adherence to the study interventions was suboptimal. Different results were reported from an observational study that assessed the impact of an "MRSA bundle" (composed of active surveillance, hand hygiene, contact precautions for MRSA colonized or infected patients) on the rates of health care–associated MRSA infections in Veterans Affairs hospitals.[317] This intervention was associated with 62 percent and 45 percent reductions in the rates of MRSA health care–associated infections in ICUs and non-ICUs, respectively. Although these two studies

have seemingly conflicting findings, differences in their design, the nature of the interventions tested, and the outcomes measures make it difficult, and potentially misleading, to compare them directly.

Another issue that has stimulated debate is the role of decolonization as a strategy to prevent health care–associated MRSA infection. Decolonization therapy has been demonstrated in multiple studies to reduce the risk for MRSA transmission (both endemic transmission and associated with outbreaks). In 2008, the Society for Healthcare Epidemiology of America recommended that this strategy be considered for patient populations or locations where the rates of MRSA health care–associated infections remain unacceptably high despite adoption of other preventive strategies.[96] To date, MRSA decolonization has not been adopted as part of routine infection prevention practices in many institutions. MRSA decolonization has also helped control outbreaks in which colonized health care workers were epidemiologically linked to MRSA transmission. In these reports, various regimens that included intranasal application of mupirocin ointment and/or the use of antiseptic baths were associated with interrupted transmission of MRSA. Although decolonization therapy can reduce the transmission of MRSA within the health care setting, multiple studies have demonstrated that a large proportion of patients and health care workers who undergo decolonization become recolonized.[188]

A recently published systematic review examined the ability of various strategies to eradicate MRSA. Intranasal mupirocin, administered daily for 4 to 7 days, had the greatest likelihood of successful eradication of MRSA carriage: approximately 90 percent probability of immediate eradication with approximately 60 percent probability of persistent eradication (although duration of follow-up assessments ranged greatly).[23] Daily bathing with chlorhexidine has also been shown to reduce the risk for MRSA colonization.[333] Factors that have been associated with failure of the ability of topical treatments to eradicate MRSA carriage include the presence of wounds, eczema, indwelling medical devices, and mupirocin-resistant MRSA.[279,618] Numerous different regimens of oral antibiotics have also been studied, in isolation or as part of a regimen that includes topical decolonization. The pooled risk for treatment failure for systemic treatment with oral antibiotics approached 50 percent, although the variation in the interventions evaluated suggest these findings may require additional study. Of note, however, was the observed rate of 9 percent drug resistance that developed in patients who received oral antibiotics.[23]

Vancomycin-Resistant Enterococci

In contrast to methicillin-resistant strains of *S. aureus*, VRE are virtually exclusively found associated with health care exposure. Patients infected with VRE infections or found to have colonization with VRE typically have identifiable exposure to high-risk health care settings, devices, or procedures. Vancomycin resistance in *Enterococcus faecium* or *Enterococcus faecalis* arises most frequently from acquisition of a mobile genetic element that carries with it the *vanA* or *vanB* resistance gene. Although exposure to vancomycin provides selection pressure that encourages the expansion of VRE in a colonized host, it does not induce a vancomycin-sensitive strain of *Enterococcus* to become resistant. However, antibiotic exposure has been repeatedly associated with an increased risk for colonization and infection with VRE. First, in a previously uncolonized patient, antibiotic use reduces populations of commensal flora, thereby lessening colonization resistance and enhancing the capacity of VRE to establish colonization in a patient who is exposed to VRE. In a patient who is already colonized with VRE, antibiotic exposure will reduce other flora and thus allow the expansion of the organism.[473] In hospitalized children, vancomycin exposure, as well as mechanical ventilation, immunosuppression, and older age were all found to be independently associated with bacteremia due to VRE, as compared with vancomycin-sensitive *Enterococcus*.[266] Three major sources have been identified as important in the transmission of VRE to patients: health care workers' hands, shared patient equipment, and the health care environment. Several observations support the importance of contaminated health care workers' hands in the transmission of VRE. First, VRE can easily be recovered from the hands and gloves of caregivers of VRE-positive patients.[488] VRE has been recovered from computer keyboards used exclusively by health care workers, again implying that hand carriage of VRE can spread the organism beyond the environment of a colonized patient.[294] Finally, having a health care worker who is simultaneously providing care to both a VRE-positive and a VRE-negative patient has been demonstrated to be a risk factor for VRE acquisition.[76] Many studies have demonstrated that VRE can persist on inanimate objects for long periods of time.[478] Thus, transmission can easily occur when a patient comes into contact with inadequately decontaminated shared patient equipment (e.g., pulse oximeters and rectal thermometers). Similarly, inadequate cleaning and disinfection of both outpatient and inpatient health care settings has been implicated in various VRE outbreaks.[75]

Prevention of transmission of VRE relies on many of the same principles used to prevent transmission of other multidrug resistant organisms within the health care setting. Similar to preventing MRSA transmission (see earlier discussion), strategies for interrupting patient-to-patient transmission of VRE rely on interrupting indirect transmission of the organism via health care workers' hands, shared patient equipment, or the health care environment. As described in the HICPAC "Management of Multidrug-Resistant Organisms in Healthcare Settings, 2006,"[609] a comprehensive approach to the control of epidemiologically important organisms, including VRE, should include the following elements: active surveillance for infection, application of standard and transmission-based isolation precautions, disinfection of the patient care environment, and judicious use of antibiotics.[609] Several studies have demonstrated the frequency of contamination of health care workers' hands or gloves after providing care for a VRE-colonized patient.[70,660] Hand cultures performed after glove removal have found that hands can become contaminated with VRE even though

gloves have been worn, presumably via unrecognized inoculation of the hand during the process of glove removal.[660] Additionally, VRE has been recovered from health care workers' hands when they only touched the environment or equipment of a VRE-colonized patient.[70] These observations support the use of gloves when care is provided to a known VRE-colonized patient and underline the importance of hand hygiene after glove removal. Transmission-based precautions (to prevent patient-to-patient spread of VRE) have also been demonstrated to reduce the prevalence of VRE among hospitalized patients.[505,644]

As with MRSA, the role of active surveillance cultures to identify the reservoir of VRE (colonized patients who have not been previously identified) has been an ongoing topic of debate. The STAR*ICU trial, described earlier, examined the capacity of active surveillance cultures of adults who were newly admitted to an ICU and expanded barrier precautions to reduce the rate of new acquisition of VRE.[311] Although these measures were not associated with reduced incidence of VRE in the intervention units, adherence to the intervention was incomplete. Thus, it is unclear whether active surveillance for VRE by obtaining cultures on admission and/or universal gloving, as compared with contact precautions used for known VRE-positive patients, can achieve greater reductions in the transmission of VRE within the health care setting.

As described previously, antibiotic exposure does not induce resistance to vancomycin in enterococcal strains that are vancomycin sensitive. However, antibiotic exposure has been associated with an increased risk for colonization or infection with VRE. To date, it remains unclear whether alterations in the agents or duration of antibiotic therapy can result in reduced prevalence of VRE. However, most experts agree that limiting the spectrum and duration of antibiotic therapy to that which is required based on the known or suspected pathogens may have a beneficial impact on the spread of many multidrug-resistant organisms through lessening of selection pressure.[609]

Multidrug-Resistant Gram-Negative Bacilli

Multidrug-resistant gram-negative bacilli (MDR-GNB) have emerged as an important cause of health care–associated infections and accounted for up to 30 percent of infections reported to the NHSN in 2006 through 2007.[293] Although the majority of these reports have come from adult institutions, pediatric health care–associated infections due to extended-spectrum β-lactamase (ESBL)–producing *E. coli* and *Klebsiella* spp., multidrug-resistant *Acinetobacter baumanii* and *P. aeruginosa*, and carbepenemase-producing Enterobacteriaceae have been reported as causes of pediatric CLABSI, catheter-associated urinary tract infections, and ventilator-associated pneumonia.[293] In the United States, outbreaks of MDR-GNB have been reported within neonatal ICUs,[654] pediatric long-term care facilities,[685] and cystic fibrosis centers.[128] Point prevalence surveys conducted by the Pediatric Prevention Network in eight U.S. pediatric ICUs and seven U.S. neonatal ICUs in 2000 found the prevalence of colonization with ESBL-producing gram-negative bacilli was less than 3 percent.[260,628] A more recent report describes the prevalence of endemic carriage of MDR-GNB in a single academic pediatric ICU. MDR-GNB (defined in this study as resistance to three or more classes of antibiotics) were carried by 3.6 percent of patients from whom active surveillance cultures were obtained.[726] The most prevalent species were *E. coli*, *P. aeruginosa*, and *Klebsiella* spp.[726] Of note, molecular analysis demonstrated very little horizontal transmission of these organisms, perhaps related to the design of the unit (all single patient rooms) and/or excellent adherence to infection prevention practices. In June 2010, the Clinical and Laboratory Standards Institute lowered the minimum inhibitory concentration breakpoints for cephalosporins and carbapenems for Enterobacteriaceae.[138] This change will undoubtedly have a marked impact on the proportion of gram-negative health care–associated infections that are caused by MDR-GNB.

Similar to other epidemiologically important drug-resistant pathogens (see earlier sections on MRSA and VRE), MDR-GNB have frequently been isolated from the environment and equipment surrounding a colonized or infected patient. Recent studies have demonstrated that these organisms are often transferred after patient contact to health care workers' gloves, gowns, and even hands after glove removal.[463] Although fewer studies have examined risk factors for endemic transmission or infection with MDR-GNB than for MRSA and VRE, outbreak investigations have frequently implicated contaminated respiratory therapy equipment (including mechanical ventilators), inappropriate use of multiuse vials of medications or diluents and urinary catheters, and inadequately cleaned patient environment as reservoirs of these organisms.[519] Additional studies have implicated exposure to broad-spectrum antibiotics, especially fluoroquinolones, with an increased risk for ESBL-producing GNB.[547,705]

The same prevention and control measures used to limit transmission of resistant gram-positive organisms within the health care setting are presumed to be effective in preventing health care–associated infections due to MDR-GNB (see earlier discussions of MRSA and VRE).[609] Hand hygiene remains the cornerstone of practices that will prevent the transmission of MDR-GNB from patient to patient. Additional measures include identifying and controlling the reservoir of these organisms, typically through the use of Standard and Contact Precautions, effective cleaning and disinfection of the shared patient equipment and the health care environment, and antimicrobial stewardship. However, active surveillance cultures for MDR-GNB are not routinely performed. Therefore, most infection prevention programs continue to rely on clinical cultures to identify patients who carry a resistant gram-negative organism. The duration of carriage of these organisms is not known but is presumed to be prolonged. Therefore, contact precautions are typically continued for patients with MDR-GNB, at least until the time of hospital discharge.[426]

Clostridium difficile

Although toxin-producing *C. difficile* is a well-recognized cause of antimicrobial-associated diarrhea in adults, we have a limited understanding of the epidemiology of *C. difficile* disease in hospitalized children. However, national data suggest that the incidence of *C. difficile* disease in patients admitted to children's hospitals is rising. In 2001 the incidence of disease was 4.4 cases per 10,000 patient-days, whereas the incidence of disease rose to 6.5 cases per 10,000 patient-days in 2006.[343]

Studies conducted in the 1980s illustrated that toxin-producing *C. difficile* can often be found in the stools of neonates and young infants.[137] Because *C. difficile* is seldom found in the stool of healthy women and clusters of colonized infants can often be detected in nurseries,[137] health care–associated transmission, as opposed to vertical transmission, is presumed to play a role in the acquisition of this microorganism by neonates developing symptomatic *C. difficile*–associated diarrhea, and some children may develop severe disease, including pseudomembranous colitis.* Disease usually occurs in association with antimicrobial therapy, and several reports have described the occurrence of the disease in children with cancer.[89,103,535,727] A prospective study of health care–associated diarrhea in hospitalized children and adolescents found that, as a group, viral causes were most common; however, *C. difficile*–associated diarrhea was the most common single cause and was more common in older children.[374]

An epidemic strain of *C. difficile* (NAP-1) emerged and disseminated in Canada and the United States during the mid 2000s that involved patients in the community and health care facilities.[401,436] This strain has caused severe disease in populations thought to be at low risk, including peripartum women and children[112]; in a study conducted in two urban areas, approximately 20 percent of the *C. difficile* isolates were the NAP-1 strain.[667]

Several studies have examined risk factors for *C. difficile* disease in hospitalized children. Solid organ transplant, presence of a gastrostomy tube, and exposure to fluoroquinolones were all independent predictors of *C. difficile* infection in children.[581] Another study examined risk factors for severe disease among hospitalized children and found that exposure to three or more classes of antibiotics was the only independent risk factor for severe disease in a cohort of hospitalized children.[342] Pediatric patients with inflammatory bowel disease have also been found to have an increased risk for recurrent *C. difficile* infection.[338] Two adult studies have explored the relationship of humoral immunity and *C. difficile*–associated diarrhea and found that patients who had serum antibodies against *C. difficile* toxin A were less like to develop disease when colonized or develop recurrent disease.[365] The implications of these findings on the epidemiology of this disease in children have not been investigated.

C. difficile can be found on the hands of personnel and in the patient's immediate environment,[248] where *C. difficile* spores can survive for prolonged periods and are relatively resistant to disinfectants. Therefore, direct or indirect contact is responsible for the spread of this microorganism from patient to patient. Barriers (gowns and gloves) and hand hygiene may reduce transmission. Vigorous environmental cleaning is important because *C. difficile* spores can heavily contaminate the environment and survive for long periods. Conventional cleaning agents may not be sporicidal, and some authorities recommend use of dilute bleach to disinfect rooms of patients with *C. difficile* infection, particularly while they have diarrhea.[248]

Unusual Pathogens Including Agents of Biologic Warfare

A variety of unusual, potentially fatal infections may be transmitted in health care settings. International air travel has increased the mobility of the world's population, making it possible for persons to travel long distances during the incubation period of infections acquired in remote settings.[594] In addition, some of the potential agents of bioterrorism are highly transmissible (e.g., smallpox virus, *Yersinia pestis*, hemorrhagic fever viruses) and could result in secondary health care–associated cases after a primary bioterrorism attack.* A high index of suspicion for these infections and prompt institution of appropriate isolation precautions are necessary to reduce the risk for health care–associated transmission.

Smallpox is the most feared of the potential agents of biological warfare because it can be transmitted via droplet nuclei over large distances, the case-fatality ratio is approximately 30 percent, there is no effective treatment, and much of the world's population is either nonimmune or was immunized in the distant past.[288] Even a very limited number of cases of smallpox would be a global public health emergency, and detailed plans for containment would be needed. Hospitalized patients with smallpox would require airborne and contact isolation precautions, and health care workers caring for these patients must be vaccinated.[288,645]

Plague is endemic in portions of the western United States and in other countries. No person-to-person transmission of plague has been identified in the United States for more than a half century,[312] but an outbreak in India illustrated the potential for importation of plague to other countries.[105] Droplet transmission of *Y. pestis* is well documented from persons with pulmonary involvement. Health care workers should wear masks during the care of patients with signs or symptoms of pulmonary involvement.[312] Tetracycline, doxycycline, sulfonamides, chloramphenicol, and perhaps fluoroquinolones can be used for prophylaxis of contacts.[312]

Ebola, Marburg, Lassa, and Crimean-Congo viruses and the New World arenaviruses have been spread in hospitals from close contact with infectious body fluids or reuse of contaminated needles.† Health care–associated

transmission of hantavirus in the United States has not been reported but has occurred with Andes virus, another cause of hantavirus pulmonary syndrome.[508] Many of the hemorrhagic fever viruses have been proposed as potential biologic weapons.[71] Of these, only Ebola, Marburg, and Lassa viruses and the New World arenaviruses are spread from person to person.[71] The bulk of evidence suggests that airborne transmission of these viruses does not occur in clinical settings, although there are insufficient epidemiologic data to exclude this possibility.[106] In 2008, the World Health Organization (WHO) issued interim recommendations for infection control for care of patients with suspected hemorrhagic fever.[716] Key recommendations include (1) limiting nonessential health care providers and visitors; (2) use of full, fluid-impervious barrier precautions, including facial protection (medical mask and goggles or eye shield); and (3) limiting unnecessary procedures and use of needles and sharp instruments.

HEALTH CARE–ASSOCIATED INFECTIONS IN SPECIAL POPULATIONS

Neonates

Most healthy term neonates are born sterile but quickly become colonized with microorganisms derived from their mothers and the immediate environment. Predominant colonizers are coagulase-negative staphylococci on the skin and umbilicus and in the nose and α-hemolytic streptococci in the mouth. Acquisition of intestinal flora is more complex. Lactobacilli predominate in breast-fed babies, whereas more "adult" flora composed of *Bacteroides* spp., other anaerobes, and *E. coli* colonizes formula-fed babies.[252] These commensals help inhibit colonization with pathogenic microorganisms. Because pathogens can spread quickly in crowded nurseries, rooming-in and early discharge reduce the risk for colonization of normal neonates.[284,413]

The timing and nature of colonization of premature and full-term infants requiring care in neonatal ICUs is substantially different than for healthy term infants. First, colonization of these infants is substantially delayed, perhaps owing to limited contact with their mothers, delayed enteral feeding, and administration of parenteral antimicrobial agents.[249,252] When colonization does occur, the type of organisms and diversity of strains is also different than those found in healthy term infants. Although coagulase-negative staphylococci colonize the skin, umbilicus, and nose of both term and preterm infants,[252] molecular typing studies have demonstrated that particular strains of coagulase-negative staphylococci can persist in neonatal ICUs over extended periods, being transmitted on the hands of caregivers and causing bloodstream infections in some infants.[308,409,517] Hospitalized neonates, as compared with healthy term infants, often have a larger proportion of intestinal flora composed of aerobic gram-negative bacilli, including *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *P. aeruginosa*, *S. marcescens*, and *Citrobacter* spp.[249,252] Antimicrobial resistant strains of these bacteria are a particular problem in many neonatal ICUs. Additionally, *Enterococcus* and *Candida* can become established on the skin and umbilicus and in the gut.[252] Because these potentially pathogenic bacteria can reach concentrations of 10^6 to 10^8 CFU/g in stool, it is not surprising that the hands of caregivers are frequently contaminated and create an important route of transmission if hand hygiene practices are lax. Unfortunately, the medical devices that help sustain these infants, such as intravascular catheters and mechanical ventilation, as well as immature skin and surgical wounds, provide portals of entry for these microorganisms to invade sterile sites and cause infection.

S. aureus remains a significant pathogen in neonates; it may colonize a variety of sites, particularly the umbilicus and nose.[252] Staphylococcal skin and soft tissue infections, including superficial skin infections, mastitis, and omphalitis, are the most common types of neonatal *S. aureus* infection. Risk factors for neonatal colonization with *S. aureus* include maternal colonization, anogenital carriage, prematurity, low birth weight, and exposure to medical devices.[324,344] Direct contact with colonized caregivers is the predominant mode of transmission. Environmental contamination, with transmission via the hands of caregivers of fomites, has also been identified as a risk factor for MRSA acquisition.[59] Indirect contact transmission from infected or colonized infants and droplet contact transmission from infants with coexisting viral respiratory tract infection (so-called cloud babies) are uncommon. Colonization of the skin, nose, umbilicus, or rectum precedes infection,[306] but there is poor correlation between rates of colonization and infection. Typically, the number of colonized infants far exceeds the number of infected infants; conversely, outbreaks of staphylococcal infection can occur in nurseries with low colonization rates. For this reason and because of cost considerations, surveillance cultures to detect colonized infants are not routinely recommended except under outbreak conditions.

MRSA has been a sporadic but recurrent problem in many neonatal ICUs for many years. However, infants in neonatal ICUs as well as otherwise healthy neonates are being affected by broader trends in the incidence of MRSA infection (see Health Care–Associated Infections Caused by Special Pathogens). Outbreaks of MRSA in neonatal ICUs have become more common, even involving multiple separate units in the same city.[247] Data from the CDC demonstrated that approximately one fourth of all *S. aureus* infections in hospitalized neonates were attributable to MRSA.[385] Risk factors for these infections include cesarean delivery (likely due to the longer postnatal hospital stay), male sex, improper infection control practices associated with circumcision, and contact with an infected health care worker.[57,113,483] Management of these outbreaks includes emphasis on standard infection control practices, such as hand hygiene, use of isolation precautions, and proper disinfection/sterilization of patient care equipment. A recent report demonstrated the capacity of whole genome sequencing to aid in the identification and management of an outbreak of MRSA in a neonatal ICU when multiple MRSA strains are present.[353] Whereas screening for colonization during the course of an outbreak is clearly useful to identify

asymptomatically colonized individuals, the role of routine screening of infants—and potentially health care workers—is less clear.[113,247]

The use of hexachlorophene (3%) for bathing is effective in reducing colonization,[254] but this agent was found to cause cystic degenerative changes in the white matter of premature infants,[531,607,608] although there was no evidence that this agent posed a hazard to full-term infants. A warning against the use of hexachlorophene was issued by the FDA in 1972.[254] Chlorhexidine is a reasonable alternative because it has good antistaphylococcal activity, and studies in neonates have demonstrated negligible absorption after bathing or cord care and no recognized toxicity. Although chlorhexidine is not currently approved by the FDA for use in infants younger than 2 months old,[8,146,328] a nationwide survey of 90 academic neonatal ICUs performed in 2009 revealed that chlorhexidine was used by over 60 percent of units. The most common indications for use included skin antisepsis at the time of dressing change and catheter insertion.[653] Use of iodophors may cause adsorption of iodine, and alcohols may cause chemical burns, so these agents should not be used for bathing. A variety of agents have been used for cord care, including triple dye (an aqueous mixture of brilliant green, proflavine hemisulfate, and crystal violet), alcohol, bacitracin, chlorhexidine, and mupirocin, although extensive efficacy and safety data are not available for any of these compounds.[254]

Fifty to seventy-five percent of women with group B streptococcal vaginal colonization will transmit this microorganism to their neonates in the absence of chemoprophylaxis, although only 1 to 2 percent of colonized infants will become infected. The CDC defines these and other infections transmitted via the birth canal as nosocomial infections.[240,242] The logic behind this designation has not been explicitly stated, but because these infections occur after an event (i.e., delivery) usually associated with medical care it is reasonable to consider them health care–associated infections. However, the impact of conventional infection control interventions on early-onset (i.e., within the first 7 days of life) invasive group B streptococcal infection is likely to be limited. Intrapartum prophylaxis of women is a far more effective intervention to reduce infection rates in neonates.[107,591] Group B streptococci can be associated with health care–associated infection not just perinatal infection. Outbreaks of group B streptococcal infection due to indirect contact transmission in nurseries have been well documented.[196,253,489]

Preterm infants are particularly susceptible to infection caused by a variety of yeasts and, to a lesser extent, filamentous fungi; *Candida* spp. are the most common fungal pathogens to infect hospitalized neonates.[30] Infants likely become colonized in gastrointestinal tracts due to carriage of *Candida*, especially *C. parapsilosis*, on the hands of health care workers.[573] Cutaneous colonization may also lead to invasive infection.[561] Risk factors for colonization with *Candida* include treatment with H_2 blockers or third-generation cephalosporins and delayed enteral feeding.[573] Risk factors for bloodstream infection and the use of prophylactic fluconazole have been discussed previously (see Infections Related to Intravascular Catheters and Infusions). Risk factors for *Malassezia furfur* infection are similar to those for *Candida*, but the association with lipid emulsion is particularly strong because this organism is obligatorily lipophilic.[159,400,556] Infections caused by filamentous fungi are rare and are usually associated with contaminated devices or practices that facilitate cutaneous invasion.[456,561]

Citrobacter koseri (previously classified as *C. diversus*) has been responsible for a number of outbreaks of health care–associated infection in neonates.[392,513,713] Although most infants colonized with this microorganism do not develop clinical disease, infection almost always results in meningitis, owing to the particular neurotropism of this bacterium, and is usually accompanied by formation of one or more brain abscesses. Sporadic outbreaks of *Citrobacter* infection have been reported,[392,513,713] and several published outbreak investigations have implicated transmission of this bacterium from the hands of caregivers to neonatal patients.[513,713] Additionally, molecular techniques have demonstrated that *C. koseri* also can be acquired perinatally by vertical transmission.[283]

Enterobacter sakazakii is a rare cause of health care–associated infection in neonates.[639] Similar to infections caused by *C. koseri*, infections caused by this bacterium are usually severe, often involving meningitis and brain abscess.* Outbreaks of *E. sakazakii* infection have implicated a variety of products,[110,370] including intrinsically contaminated powdered milk formulas.[64,110,474,614,675] Because powdered formulas are not marketed as sterile products, feeding practices in neonatal ICUs need to balance the relative nutritional benefits of particular products against the small but real risk for infection with *E. sakazakii* and other potential pathogens.

New obstetric practices, such as water birth, may pose infectious threats to infants, as demonstrated by the report of a case of *Legionella* pneumonia in an infant after a prolonged delivery in a pool with contaminated water.[221] Similarly, the emerging field of fetal surgery may also introduce the new condition of a surgical site infection in an unborn child.

Hand hygiene is the most effective intervention to prevent spread of pathogenic microorganisms.[77] However, the hands of some staff may remain colonized with these microorganisms for prolonged periods despite scrupulous hand cleansing[252] In addition, use of artificial nails or nail wraps has been associated with carriage of *P. aeruginosa* on the hands of health care workers in a neonatal ICU.[217] Therefore, healthcare workers should not be allowed to wear artificial nails or nail wraps when providing hands-on patient care.[572] Alcohol-based hand rubs are the most effective agents in reducing hand colonization with pathogenic bacteria and are the preferred method for hand hygiene when hands are not visibly soiled.[77]

Preceding sections contain specific recommendations for the prevention of health care–associated infections caused by community pathogens and infections related to the use of invasive devices. Other general references regarding the prevention of infections in normal nurseries and neonatal ICUs have been published, including recommendations regarding the design of facilities,

*References 64, 110, 134, 370, 614, 675.

appropriate staffing, and general infection prevention procedures.[20,140]

Several interventions designed specifically to prevent health care–associated infection in high-risk infants deserve additional comment.

The Vermont Oxford Network Evidence-Based Quality Improvement Collaborative for Neonatology is a large multicenter network of neonatal units organized for the purpose of implementing evidenced-based interventions to improve the quality of care of neonates.*[302] Data from a group of 669 neonatal ICUs spanning the years 2000 through 2009 describe a significant reduction in late bacterial infections; in 2000, 21.1 percent of surviving infants weighing 501 to 1500 g experienced a late bacterial or fungal infection, whereas the rate of late infections was 15.0 percent in similar infants in 2009.[301]

Many investigators have purposefully colonized infants in neonatal ICUs with nonpathogenic microorganisms, including viridans streptococci and *Lactobacillus*, to "interfere" with colonization by potential pathogens.[254,448,551] Some of the studies using viridans streptococci demonstrated favorable results, but this approach has not been pursued, in part owing to concern about the potential for adverse events.[254] Studies using *Lactobacillus* have demonstrated little or no beneficial effect.[448,551]

Infants of extremely low birth weight have immature, fragile skin that is predisposed to drying and cracking and may not be an adequate barrier to prevent invasion by bacteria colonizing the skin. For this reason, products containing emollients that include fatty acids have been developed to reduce transepidermal fluid loss and improve skin barrier function in very-low-birth-weight infants. A randomized controlled trial of the effect of an emollient ointment (Aquaphor) in infants with a birth weight of 501 to 1000 g and a gestational age of 30 weeks or younger was conducted in 53 neonatal ICUs participating in the Vermont Oxford Network.[199] The study found that treated infants had better skin condition on days 1 to 14 of life and less skin injury on days 15 to 28 of life. However, the treatment group had a higher rate of late-onset bacterial sepsis, with the majority of excess cases occurring in infants 501 to 750 g. There was no effect on mortality. In contrast, two randomized controlled trials conducted in Bangladesh found that sunflower seed oil reduced the rate of late-onset infection and mortality in preterm infants with a gestational age of 33 weeks or younger.[160,162] Interestingly, the second of these trials included Aquaphor as a comparator treatment and found a similar decrease in mortality associated with application of this agent. An additional study conducted during the second trial provided indirect evidence that the treatment effect was likely mediated by decreased passage of skin pathogens into the bloodstream.[161]

Because premature infants lack sufficient levels of opsonizing antibodies, multiple trials have examined the efficacy of intravenous immunoglobulin in preventing infection in premature infants.[42,208,345,416,702] Only one of these trials demonstrated any benefit in reducing overall infection rates.[42] A large trial that randomized almost 3500 infants with suspected or proven infection found therapy with intravenous immunoglobulin had no impact on death or major disability.[84] An evaluation of commercially available intravenous immunoglobulin preparations found a large degree of variability in opsonic activity against common neonatal pathogens between individual lots produced by the same manufacturer as well as preparations from differing various manufacturers.[701] The impact of high-titer, pathogen-specific antibody preparations in the prevention of invasive infection by specific neonatal bacterial pathogens remains unclear.

Because preterm infants have limited neutrophil pools as well as limited neutrophil function, several randomized, controlled studies have examined the prophylactic and therapeutic effect of granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) on infections in preterm infants. In all of these studies, infants receiving these agents had higher peripheral blood neutrophil counts than infants receiving placebo. However, the evidence of the beneficial effects of treatment with these agents is limited.[95,102,457]

Leukocytes present in stored blood products may have adverse effects on immune function, especially in preterm infants. However, a study examining the effect of universal prestorage red blood cell leukoreduction program found no effect on bloodstream infection and mortality but was associated with improvements in other clinical outcomes.[211] Use of postnatal corticosteroids to prevent or treat chronic lung disease in preterm infants has been associated with higher rates of health care–associated infection,[640] as well as other short- and long-term adverse outcomes.[142]

Immunocompromised Children

Children with congenital or acquired immunocompromising conditions are at high risk for health care–associated infections. The risk for these infections is related to host factors, such as the nature and severity of immunocompromise, use of indwelling medical devices, and frequency and nature of exposure to the health care environment.

The epidemiology of and risk factors associated with health care–associated infections in immunocompromised children have been best characterized for children with oncologic conditions. Investigators from St. Jude Children's Research Hospital have described the changes in the incidence of health care–associated infections among their patients hospitalized from 1983 through 2008.[435] In 2008, the overall infection rate was 2.0 per 100 patient discharges; CLABSI comprised approximately one third of all identified health care–associated infections. Neutropenia was identified as a risk factor associated with health care–associated infections; the risk for health care–associated infection was threefold greater among patients with a nadir absolute neutrophil count of less than 100 cells/mm^3 as compared with patients with less profound neutropenia. A single-center study also found that platelet transfusion and recent catheter placement were risk factors for CLABSI in pediatric oncology patients.[337]

*Vermont Oxford Network Evidence-Based Quality Improvement Collaborative for Neonatology: http://www.nicq.org.

The risk for health care–associated infections in children undergoing bone marrow or solid organ transplantation can be influenced by factors related to the patient's underlying health status, microbiologic characteristics of the donor and recipient of the graft, the duration and nature of immunosuppression required for successful engraftment of the transplanted organ, and the duration and nature of exposure to medical devices and the health care setting.[337] Solid organ transplant recipients are at risk for bacterial and fungal infections associated with the use of medical devices or in the surgical wound. Severe manifestations of common childhood viruses, such as CMV and RSV, also can pose a threat to a child who has recently undergone organ transplantation.

For immunocompromised children with indwelling medical devices or who undergo surgery or invasive procedures, the same strategies described earlier should be employed to prevent health care–associated infections. For children with nonpermanent immunocompromising conditions (e.g., those receiving chemotherapy or initiating antiretroviral therapy), all elective surgeries and invasive procedures should be deferred until their immunocompromised state has resolved.

The increased susceptibility to opportunistic pathogens necessitates heightened infection prevention measures for some children with the most profound degree of immunosuppression. Numerous outbreaks due to low-virulence organisms commonly found in the environment, such as mold infections related to construction in or near a health care facility have been reported.[687] Because airborne fungal spores can enter the health care environment, the CDC recommends placement of the most severely immunocompromised patients, such as neutropenic patients undergoing allogeneic stem cell transplantation, in an environment with added engineering measures to provide additional protection (i.e., a protective environment). Critical components of a protective environment include (1) positive-pressure patient care environment; (2) high-efficiency particulate air filtering; (3) selective air-handling units; and (4) high numbers of air exchanges per hour (>12 per hour).[594] Despite the broad adoption of these recommendations by many centers that care for high-risk oncology patients in the United States, relatively few studies have demonstrated the effectiveness of these measures. A recently published meta-analysis was unable to demonstrate that measures to control the air quality reduced the risk for invasive mold infections,[590] and a systematic review described an association between high-efficiency particulate air filtration and a reduction in fungal infections only when their analysis was limited to nonrandomized studies.[197]

Children with Burns

Information regarding the epidemiology of health care–associated infections in pediatric burn patients has been described in four reports,[147,241,589,696] including the experience of a single pediatric burn facility that performed prospective surveillance using modified CDC definitions.[696] A total of 14 percent of patients experienced an infection that was associated with an incidence density of 16 infections per 1000 patient-days.[696] Infection of the burn wound was observed in 10 percent of patients for an incidence density of 5.6 burn infections per 1000 patient-days. In this report, the rates of device-associated infections were 4.9 bloodstream infections per 1000 central venous catheter-days, 11.4 cases of ventilator pneumonia per 1000 ventilator-days, and 13.2 urinary tract infections per 1000 urinary catheter-days. These rates are higher than the most recently published pooled means for adult burn units.[194] Although comparable data are not available for dedicated pediatric burn units, it is reasonable to presume that similar reductions in health care–associated infections have also been achieved in pediatric burn centers. New definitions for burn infection were developed and endorsed by a consensus conference convened by the American Burn Association[257] and have been incorporated into NHSN definitions.[300]

The risk and microbiology of burn infections are related to the size of the burn wound and the time of onset of the infection. Infections in burn patients can arise from either endogenous organisms (often organisms colonizing the wound) or exogenous organisms. Colonization of a burn typically proceeds from gram-positive organisms, antibiotic-susceptible gram-negative organisms, and finally fungal and antibiotic-resistant gram-negative organisms.[542] Gram-positive cocci, including methicillin-susceptible and methicillin-resistant *S. aureus*, were the most common cause of burn infection in patients with relatively small burns (<30% of body surface area), whereas gram-negative bacteria (especially *P. aeruginosa*) were more common causes of infection in patients with extensive burns (>30% of body surface area).

Interventions to reduce the incidence of health care–associated infections in burn patients include the use of barrier techniques to reduce cross colonization of patients, measures to prevent cross colonization of patients during hydrotherapy treatments, topical antibiotics to retard growth of microorganisms in the burn wound, appropriate use of systemic antibiotics, and early excision and closure of the burn wound. The success of the Shriners Burns Hospital in Boston in controlling infections in severely burned children using these methods and "bacteria-controlled nursing units" (a laminar airflow unit providing controlled temperature and humidity combined with barrier precautions) has been described.[697] Finally, a randomized, controlled trial of selective decontamination of the digestive tract using polymixin E, tobramycin, and amphotericin B in severely burned children found no evidence of benefit.[44]

Children with Cystic Fibrosis

In 2003, Saiman and colleagues reviewed the epidemiology of important pathogens in persons with cystic fibrosis in a document summarizing the conclusions of an international consensus conference convened to develop evidence-based guidelines for standardized microbiologic and infection control practices for persons with cystic fibrosis.[575] They concluded that there was substantial evidence for transmission of *Burkholderia cepacia* complex, *P. aeruginosa*, and MRSA among persons with cystic fibrosis in health care settings, but that there was insufficient evidence to determine whether *Stenotrophomonas*

maltophilia, *Achromobacter xylosoxidans*, nontuberculous mycobacteria, or filamentous fungi could be transmitted from person to person. At the time of this writing, an expert panel is drafting revised infection control recommendations for patients with cystic fibrosis.

The recommendations from the 2003 consensus guideline emphasize standard infection control practices in the care of patients with cystic fibrosis, including appropriate hand hygiene and use of barriers by health care workers, proper use of isolation precautions, and effective procedures for cleaning and disinfecting/sterilizing reused equipment contaminated with respiratory secretions.[575]

In inpatient settings, the 2003 guideline recommends contact isolation and a private room for patients who are colonized or infected with MRSA, *B. cepacia* complex, and multidrug-resistant *P. aeruginosa*. Patients who are not colonized with these bacteria may share a room with a patient who does not have cystic fibrosis and who is at low risk for infection with these bacteria. All patients, whether colonized with these bacteria or not, should avoid contact with other patients with cystic fibrosis.

The 2003 guideline makes no recommendation regarding the use of masks by patients with cystic fibrosis either in inpatient or outpatient settings owing to lack of sufficient evidence for or against the efficacy of this practice.[575] However, a survey of 158 cystic fibrosis centers performed in 2004 found that many of the responding institutions had policies that advocated the use of masks when a patient was out of their hospital room (69%) or in the clinic waiting area (35%).[723]

In ambulatory settings, the 2003 guideline recommends that patients with cystic fibrosis who are colonized or infected with *B. cepacia* complex should be segregated from other cystic fibrosis patients and other patients colonized or infected with *B. cepacia* (to avoid replacement of one strain with another), their visits should be scheduled at the end of the clinic session or on another day, and they should be placed in an examination room immediately on arrival to the clinic instead of sitting with other patients in the waiting room.[575] Patients colonized or infected with multidrug-resistant *P. aeruginosa* should also be placed in an examination room immediately. For other patients with cystic fibrosis, the 2003 guideline recommends a variety of clinic logistics to minimize the time patients spend in waiting areas and emphasizes education of patients regarding appropriate waiting area behaviors to minimize contact among patients (e.g., discouraging handshakes and physical contact among patients, maintaining at least 3 feet between patients, avoiding contact with common-use items). Finally, all patients should receive annual influenza vaccination and age-appropriate pneumococcal vaccination.

Children Undergoing Dialysis

Children with chronic renal failure who are undergoing either hemodialysis or peritoneal dialysis have multiple risk factors for health care–associated infections. First, renal failure is associated with impaired immune function, including phagocyte dysfunction due to uremia. Children with renal failure often require frequent contacts with the health care system, including hospitalization, further increasing the risk for acquiring multidrug-resistant organisms. Finally, the indwelling medical devices required for dialysis pose additional risks. Studies of adult patients with end-stage renal disease have demonstrated an increased risk for infection associated with the presence of an immunocompromised condition (related to either an underlying disease process or use of immunosuppressing therapies), anemia, or iron overload.[40]

Infection of dialysis access devices, whether for hemodialysis or peritoneal dialysis, remains the most common type of health care–associated infection experienced by patients with end-stage renal disease.[40] In hemodialysis patients, the risk for bacteremia is influenced by the type of vascular access device in use. Arteriovenous fistulas are associated with the lowest risk for bacteremia, in contrast to nontunneled dialysis catheters, in which the risk for bacteremia has been reported to approach 22.5 infections per 1000 dialysis procedures, which is 7- to 10-fold higher than the rate of infections reported for patients undergoing dialysis via an arteriovenous fistula during the same time period.[295,659] In addition, adult studies have demonstrated that comorbid conditions (particularly diabetes mellitus and hypertension) are independently associated with an increased risk for bacteremia in patients undergoing hemodialysis.[384] Gram-positive organisms are the most common cause of bacteremia in patients undergoing hemodialysis; *S. aureus* and coagulase-negative staphylococci are the most frequently isolated pathogens.

Many of the same practices used to prevent catheter-associated bloodstream infections in patients with conventional central venous catheters are considered standard of care for patients with hemodialysis catheters. However, several important differences should be noted. In contrast to exit sites for conventional venous catheters, current guidelines recommend that antiseptic or antibacterial ointment (either povidone-iodine or bacitracin/gramicidin/polymyxin B) be placed at the exit site of hemodialysis catheters after insertion and after each dialysis session provided the catheter material is compatible with this substance.[494] Recent efforts to increase the use of arteriovenous fistulas and improve the access techniques have resulted in substantial reductions in the rate of bacteremia in adult dialysis patients. For hemodialysis patients with a history of multiple episodes of bacteremia, several meta-analyses[369,720] and a recent randomized trial have demonstrated that use of antibiotic or antiseptic locks between dialysis sessions were associated with a reduced risk for subsequent bacteremia.[630] Although few data are available from studies of pediatric patients, application of these same strategies to pediatric patients undergoing hemodialysis patients is also likely to reduce the risk for bacteremia in this patient population.

Peritonitis is the most common health care–associated infection in patients undergoing either intermittent or continuous peritoneal dialysis. In addition to raising the risk for infection-related death, peritonitis poses long-term risks to patients who require chronic dialysis;

repeated or protracted episodes of inflammation of the peritoneum can result in permanent fibrosis of the peritoneal membrane and render peritoneal dialysis ineffective. Recent pediatric data suggest gram-positive organisms account for 44 percent of cases of culture-positive peritonitis; approximately half of the gram-positive isolates were *S. aureus*, whereas the remaining isolates were coagulase-negative staphylococci. Approximately 50 percent of pediatric peritonitis in this population is due to gram-negative organisms, whereas less than 5 percent of episodes are due to fungi.[123]

Using data from the International Pediatric Peritoneal Dialysis Registry, the International Society for Peritoneal Dialysis has published guidelines for the treatment and prevention of peritonitis in pediatric patients.[690] These guidelines recommend that antibiotics be administered via the intraperitoneal route for the treatment of peritonitis. Empirical antibiotics should be selected based on available data on local resistance patterns of likely infecting organisms. Vancomycin is not routinely recommended for empirical therapy unless the institution's rate of MRSA exceeds 10 percent or the patient has a history of MRSA colonization or infection.[690] Definitive therapy should be tailored once the organism has been isolated and susceptibility data are available. The recommended duration of therapy varies based on the infecting organism but ranges from 2 to 3 weeks for most bacterial pathogens. Replacement of the peritoneal catheter is recommended for cases of refractory or relapsing bacterial peritonitis, in the setting of a tunnel infection, and for fungal peritonitis.

Prevention of health care–associated infection in children undergoing peritoneal dialysis rests on the same principles used to prevent intravascular infections: scrupulous adherence to aseptic technique during catheter insertion and access, and close attention to the care of the catheter exit site. Please refer to the recently published pediatric peritoneal dialysis guidelines for detailed recommendations.[690]

Children in Long-Term Care Facilities

In the preceding sections we have described a variety of microorganisms that have caused disease in long-term care facilities for children, including various viral infections and enteric pathogens that typically cause community-onset infections. Specific interventions to prevent these infections have been discussed previously.

Several reports have described the burden and spectrum of health care–associated infections among children in long-term care facilities. A single-center study, performed in 2009, reported the incidence of health care–associated infections among residents of a 109-bed pediatric long-term care facility as 6.01 infections per 1000 resident-days.[3] A prospective, longitudinal study of four pediatric facilities described the spectrum of endemic nosocomial infections in this population over a 2-year period in the 1990s.[684] The cumulative incidence of infection was 40 percent; upper respiratory tract infections and urinary tract infections were the most common types of infection and accounted for 37 percent and 31 percent of infections, respectively. In this report, nearly 80 percent of the urinary tract infections occurred in a small group of patients with functional and/or anatomic genitourinary abnormalities related to neural tube defects or neuromuscular disorders. This study, however, did not differentiate between symptomatic infections and asymptomatic bacteriuria. A more recent report described the burden of device-related infections in this population.[282] The incidence of catheter-associated urinary tract infection was more than twice as frequent as in pediatric ICUs reporting data to the National Nosocomial Infections Surveillance System, whereas the incidence of ventilator-associated pneumonia and central venous catheter-associated bloodstream infections were equivalent or slightly lower than that reported in pediatric ICUs. Other findings from these studies include the relatively high frequency of upper and lower respiratory tract infections among young children with tracheostomies and that skin infections accounted for 16 percent of infections (however, the specific percentage of decubitus ulcers was not reported). Gastrointestinal infections were remarkably uncommon; in contrast to adult facilities where infections due to *C. difficile* and outbreaks of norovirus are relatively common, these authors reported that gastrointestinal infections comprised only 4 percent of all infections. However, it is unclear whether detection bias may have led to underrecognition of these types of infections. Because of the heterogeneity in the populations of patients served and the ongoing improvement efforts underway at virtually all sites where health care is provided, readers would be advised to exercise caution when selecting a benchmark to which to compare their facility's rates of health care–associated infections.

Guidelines for the infrastructure and essential activities of infection control programs and key prevention practices in long-term care facilities have been published, although these documents do not deal with issues specific to the care of children.[227,624,625]

Key prevention measures are effective hand hygiene, appropriate use of barriers and isolation precautions, proper care of patients with indwelling devices (e.g., tracheostomies) or who require invasive procedures (e.g., bladder catheterization), prevention of decubitus ulcers, age-appropriate immunization (including yearly influenza vaccine), and early detection and control of outbreaks of infection.

INFECTION PREVENTION AND CONTROL PROGRAMS IN HEALTH CARE FACILITIES

This section highlights key elements of a comprehensive program to prevent and control health care–associated infections in health care facilities that provide inpatient care for pediatric patients. A detailed description of the development, implementation, and maintenance of an effective program is beyond the scope of this chapter, and the reader is referred to several excellent and authoritative references on this topic.[320,376,433,706]

Many external groups and organizations have significant influence on infection prevention and control programs in health care facilities; their activities are outlined in Table 243-8.

Organization and Activities of Health Care Infection Control Programs

In 1998, a consensus panel of national experts published a report on the requirements for infrastructure and activities of health-care–associated infection prevention and control programs.[587] The specific recommendations of the panel are listed in Table 243-9, accompanied by an indication of the strength of the recommendation, and are described in more detail in the report.[587] A similar document outlining the elements of infection prevention and control in long-term care facilities has also been published.[624] These publications do not deal specifically with pediatric issues, although the recommendations are generally applicable to facilities providing care to children.

Surveillance Strategies

Surveillance of health care–associated infections is necessary to understand the specific infection problems of individual facilities, to provide a means of evaluating the effectiveness of interventions to reduce the frequency of these infections, and to facilitate detection of outbreaks of infection. Infection prevention and control programs should have a surveillance plan for their health care facility that is based on the prioritized risks associated with care provided to patients in their facility and sound epidemiologic principles.[383]

The CDC NHSN surveillance methodology has become the de facto standard for surveillance. Although not without limitations, this methodology is well defined and time tested and allows institutions to benchmark themselves to other institutions through periodic data summaries from the NHSN as a whole.[194] In addition, NHSN methodology is used extensively by states and by the Center for Medicare and Medicaid Services for public reporting of rates of health care–associated infections (see Table 243-8). The NHSN has published definitions for health care–associated infections[300] with detailed instructions on the application of its methods.* Readers should refer to the NHSN website for the latest updates in NHSN definitions and methodology.†

Surveillance should also examine adherence to processes that are tightly linked to outcomes. As examples, facilities should monitor adherence with recommendations for hand hygiene and transmission-based isolation precautions,[82,584] "all-or-none" use of intervention bundles to prevent CLABSI and ventilator-associated pneumonia,[65,452,487,534] and administration of perioperative antimicrobial prophylaxis for prevention of surgical site infections.[81] These process measures can be used to guide and monitor process improvement efforts.

Surveillance and reporting of communicable infections to state departments of health is a duty of infection prevention and control programs and often done in collaboration with their microbiology laboratory.

Outbreak Investigation

Because outbreaks of health care–associated infections are often associated with significant patient morbidity and mortality, clusters of infection should be investigated promptly. A single, highly unusual infection, such as a postoperative group A streptococcal infection, is sufficient cause for an investigation. Clusters of health care–associated infections caused by an uncommon microorganism, a common microorganism with an unusual antimicrobial susceptibility pattern, or a series of infections at the same anatomic site (i.e., an outbreak of diarrhea) also are indications for an investigation. However, some outbreaks are more difficult to recognize because they occur intermittently, involve multiple microorganisms, or involve infection at various anatomic sites.

Table 243-10 provides an outline of the steps involved in investigating a cluster of health care–associated infections. Detailed discussions of the methodology for outbreak investigation also are found in other references.[47,320,376,433,706] Published outbreak investigations are also an invaluable resource because they provide insight into potential causes. For example, an outbreak caused by *Stenotrophomonas (Xanthomonas) maltophilia*, *Burkholderia cepacia*, or *Pseudomonas* spp. should suggest the possibility of a common source outbreak owing to a contaminated solution or medication or an inadequately disinfected piece of equipment. On the other hand, it is hazardous to jump to conclusions regarding the cause of a particular cluster of infections based on the results of a prior investigation. Careful investigation is necessary to establish or refute epidemiologic links between cases and potential causes.

Molecular genotyping techniques are an important adjunct to traditional epidemiologic methods (e.g., cohort or case-control studies) and can serve as a powerful tool to confirm or refute a particular source or mode of transmission of a particular microorganism. Two reports have described the use of whole-genome mapping in outbreak investigations, one involving MRSA infections in a neonatal ICU and the other involving carbapenemase-resistant *Klebsiella pneumoniae* infections in a specialty hospital.[353,626] In both cases, whole-genome mapping provided important additional insight into the spread of these organisms.

Policies and Procedures

Policies and procedures are necessary to optimize and standardize hospital routines and patient care practices. Certain generic policies and procedures apply to all departments, such as those for hand hygiene, isolation

TABLE 243-8 **External Groups and Organizations Influencing Health Care–Associated Infection (HAI) Prevention and Control Programs**

Group/Organization	Activities
Division of Healthcare Quality Promotion (DHQP), National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention (CDC)	Provides data and guidance on prevention of HAIs; antimicrobial resistance; adverse drug events; blood, organ and tissue safety; and immunization safety; and other related adverse events or medical errors in health care affecting patients and health care personnel
	Investigates and responds to emerging infections and related adverse events among patients and health care personnel
	Conducts epidemiologic, and basic and applied laboratory research to identify new strategies to prevent HAIs, antimicrobial resistance, and related adverse events or medical errors
	Serves as the national reference laboratory for the identification and antimicrobial susceptibility testing of pathogens that cause HAIs
National Healthcare Safety Network (NHSN)	Collects and reports data on the incidence of HAIs, antimicrobial use and resistance, and process measures tightly linked with prevention of HAIs
Healthcare Infection Control Practices Advisory Committee (HICPAC)	Provides guidance to DHQP regarding surveillance, prevention, and control of HAIs; publishes evidence-based guidelines for HAI prevention
United States Department of Health and Human Services	Develops the "National Action Plan to Prevent Healthcare-Associated Infections: Roadmap to Elimination" that includes components for acute care hospitals, ambulatory surgical centers, end-stage renal disease facilities, and long-term care facilities
Center for Medicare and Medicaid Services	Requires reporting of some HAIs by facilities providing care to Medicare and Medicaid beneficiaries
	Leads the "Partnership for Patients," which has a goal of a 40% reduction in preventable harms, including HAIs, by the end of 2013
State health departments	Require public reporting of institutional rates of HAIs, with specifics varying by state
Professional societies	Advocate for public policy related to prevention of HAIs
Society of Healthcare Epidemiology of America (SHEA)	Develop and collaborate on publication of evidence-based guidelines for HAI prevention
Association for Professionals in Infection Control and Epidemiology (APIC)	Provide training for health care epidemiologists and infection preventionists
Infectious Diseases Society of America (IDSA)	Sponsor scientific meetings on HAI prevention
	Publish journals including articles on HAI prevention
The Joint Commission	Provides accreditation standards for infection prevention and control programs; promulgates National Patient Safety Goals, which includes goals related to prevention of HAIs
National Quality Forum	Selects measures of health care quality
United States Department of Labor's Occupational Safety and Health Administration (OSHA)	Issues regulations to minimize occupational hazards to health care workers, including exposure to bloodborne pathogens and tuberculosis
Institute of Medicine	Publishes scientific reports related to improving patient safety and reducing HAIs
Institute for Healthcare Improvement (IHI)	Provides guidance documents on performance improvement regarding patient safety, including preventing HAIs
	Conducts campaigns to improve patient safety
	Provides training for patient safety officers
Children's Hospital Association	Coordinates performance improvement collaboratives to reduce HAIs
Vermont Oxford Network	Collects and reports outcomes of neonatal care, including late-onset sepsis
	Coordinates improvement collaboratives to improve outcomes, including reducing late-onset sepsis
National Surgical Quality Improvement Project	Coordinates an outcomes-based program to measure and improve the quality of surgical care, including prevention of surgical site infections
Consumers Union	Publishes reports and ranking of hospitals with respect to HAI prevention
	Advocates for patient safety

TABLE 243-9 **Consensus Panel Recommendations Regarding the Requirements for Infrastructure and Essential Activities of Infection Control and Epidemiology in Hospitals**

Recommendation	Category*
Critical Data and Information	
Surveillance of nosocomial infections must be performed.	I
Surveillance data must be analyzed appropriately and used to monitor and improve infection control and health care outcomes.	I
Clinical performance and assessment indicators used to support external comparative measurements should meet the criteria delineated by SHEA and APIC.	II
Policies and Procedures	
Written infection prevention and control policies and procedures must be established, implemented, and updated periodically.	II and III
Policies and procedures should be monitored periodically for performance.	II and III
Regulations, Guidelines, and Accreditation Requirements	
Health care facilities should use infection control personnel to assist in maintaining compliance with relevant regulatory and accreditation requirements.	II
Infection control personnel should have appropriate access to medical or other relevant records and to staff members who can provide information on the adequacy of the institution's compliance with regard to regulations, standards, and guidelines.	II
The infection control program should collaborate with, and provide liaison to, appropriate local and state health departments for reporting of communicable diseases and related conditions and to assist with the control of infectious diseases.	II and III
Employee Health	
The infection control program personnel should work collaboratively with the facility's employee health program personnel.	II
At the time of employment, all facility personnel should be evaluated by the employee health program for conditions relating to communicable diseases.	II and III
Appropriate employees or other health care workers should have periodic medical evaluations to assess for new conditions related to infectious diseases that may have an impact on patient care, the employee, or other health care workers, which should include review of immunization and tuberculosis skin test status, if appropriate.	II and III
Employees must be offered appropriate immunizations for communicable diseases.	I and III
The employee health program should develop policies and procedures for the evaluation of ill employees, including assessment of disease communicability, indications for work restrictions, and management of employees who have been exposed to infectious diseases, including postexposure prophylaxis and work restrictions.	I
Prevention of Transmission of Infectious Diseases	
All health care facilities must have the capacity to identify the occurrence of outbreaks or clusters of infectious diseases.	I
All health care facilities must have access to the services of personnel trained and experienced in conducting outbreak investigations.	II
When an outbreak occurs, the infection control team must have adequate resources and the authority to ensure a comprehensive and timely investigation and the implementation of appropriate control measures.	II
Education and Training of Health Care Workers	
Health care facilities must provide ongoing educational programs in infection prevention and control to health care workers.	II and III
Educational programs should be evaluated periodically for effectiveness, and attendance should be monitored.	II and III
Personnel	
The personnel and supporting resources, including secretarial services, available to the hospital epidemiology and infection control program should be proportional to the size, complexity, and estimated risk for the population served by the institution.	II
All hospitals should have the continuing services of a trained hospital epidemiologist(s) and infection control professional(s).	I
Infection control professionals should be encouraged to obtain certification in infection control.	II
Health care facilities should provide or make available, in a timely fashion, sufficient office space, equipment, statistical and computer support, and clinical microbiology and pathology laboratory services to support the surveillance, prevention, and control program of the institution.	II

*I, strongly recommended for implementation based on evidence from at least one properly randomized, controlled trial, or evidence from at least one well-designed clinical trial without randomization, or evidence from cohort or case-control analytic studies (preferably from more than one center) or evidence from multiple time-series studies; II, recommended for implementation based on published clinical experience or descriptive studies, or reports of expert committees, or opinions of respected authorities; III, recommended when required by government rules or regulations

TABLE 243-10 Approach to the Investigation of Clusters of Health Care–Associated Infections

1. Confirm the diagnosis.
2. Make a case definition.*
3. Search for additional cases.
4. Plot the epidemic curve.
5. Compare pre-epidemic rates to current rates using statistical tests to prove that an epidemic exists.
6. Perform a literature review.
7. Open lines of communication with leaders of relevant departments, the microbiology laboratory, and the hospital administration.
8. Keep detailed records of events and conversations.
9. Review charts of all cases and compile a line listing of relevant information.
10. Formulate a hypothesis about a likely reservoir and mode of transmission.*
11. Institute temporary control measures.
12. Perform a case control study to develop epidemiologic evidence to support or refute the hypotheses.
13. Update control measures.
14. Document the reservoir and mode of transmission microbiologically. Confirm the relatedness of isolates using molecular genotyping techniques if necessary.*
15. Document the efficacy of control measures.
16. Write a report and distribute it to appropriate individuals.
17. Change policies and procedures if necessary.

*Molecular genotyping techniques may be employed early in the course of the investigation to evaluate the relatedness of pathogens associated with the cluster, reservoirs, and modes of transmission.

precautions, prevention of transmission of infectious diseases from and to visitors and health care workers, reprocessing of reusable patient care items, and disposal of medical waste. Other policies and procedures should be tailored to the potential infection risks relevant to specific departmental activities. Individual guidelines on various topics published by the HICPAC,* a compendium of guidelines on the prevention of health care–associated infections in acute care hospitals published by the Society for Healthcare Epidemiology of America (SHEA,)† and guidelines published by other professional societies (see Table 243-8) serve as useful references for these efforts.

However, merely developing policies, procedures, and standardized practices is insufficient. Indeed, recent achievements in prevention of health care–associated infections have been due primarily to improvement in reliably incorporating evidence-based practices as a part of routine patient care.[65,452] Effective leadership and application of principles and practices of implementation and improvement science are critical to the success of these efforts.[310,577,578]

Hand Hygiene

Proper hand hygiene, which includes both hand washing using soap and water and hand antisepsis using a waterless, alcohol-based agent, reduces carriage of potential pathogens on the hands of health care workers.[77,525] Hand hygiene is widely regarded as the quintessential infection prevention measure.

Indications and procedures for hand hygiene are reviewed in detail in both a HICPAC guideline and a guidance document produced under the auspices of the WHO.[77,585] The WHO approach was developed as a "user-centric" model and has five "moments" for hand hygiene: before patient contact; before performing an aseptic task; after actual or potential contact with body fluids; after contact with the patient or his or her immediate surroundings; and after contact with the patient care environment outside the immediate surroundings.[585] Hand washing with soap and water must be performed when hands are visibly soiled to remove organic material and associated microorganisms. When hands are not visibly soiled, hand antisepsis using an alcohol-based, waterless product is preferred because it reduces the number of pathogenic bacteria that transiently colonize the hands more effectively than hand washing.[77,526] Hand hygiene is also necessary after removing gloves—an indication that many health care professionals fail to fully appreciate—because gloves may have macroscopic and microscopic holes that lead to hand contamination and because hands may be contaminated in the process of removing soiled gloves.[352]

The WHO has also provided a strategy for measurement of adherence with the five moments and behavior change strategies to improve adherence.[584,710]

Persons wearing artificial nails are more likely to harbor pathogenic gram-negative bacilli and yeast on their fingertips and these organisms are less effectively cleared on artificial nails by use of an alcohol-based agent than on natural nails.[285,440] Use of artificial nails or nail wraps was associated with carriage of *P. aeruginosa* on the hands of health care workers and infection among high-risk infants in a neonatal ICU.[217,263] For these reasons, the HICPAC hand hygiene guideline recommends that health care workers not wear artificial fingernails or extenders when providing patient care and that natural nails should be kept less than ¼ inch long.[77]

Isolation Precautions

Proper utilization of isolation precautions is important for all health care facilities but is especially critical in facilities caring for pediatric patients. Children hospitalized as the result of infections acquired in the community represent a substantial proportion of pediatric admissions, and transmission of these infections to other susceptible patients is a significant problem (see earlier discussion under Health-Care–Associated Infections Due to Spread of Communicable Infections Common in Health Care Facilities). Effective use of appropriate isolation precautions markedly reduces transmission of these agents.

The HICPAC isolation guideline recommends use of two tiers of precautions, Standard Precautions and Transmission-Based Precautions.[609,610]

Standard Precautions

Standard Precautions synthesizes the goals of protecting health care workers from bloodborne pathogens and protecting health care workers and patients from transmission of microorganisms from moist body substances.[610] Standard Precautions apply to any planned or potential contact with blood; all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; nonintact skin; mucous membranes; and supplies, equipment, or surfaces contaminated with these substances (see Table 243-1). Standard Precautions should be used in the care of all patients at all times regardless of their diagnosis or presumed infection status.[610]

Transmission-Based Precautions

Other precautions are needed to prevent transmission of contagious diseases (e.g., varicella, measles, tuberculosis, and pertussis) and other epidemiologically important microorganisms (e.g., multidrug-resistant microorganisms, *C. difficile*) from infected or colonized patients. Transmission-Based Precautions are designed to provide the necessary measures, in addition to those already specified by Standard Precautions, to interrupt known modes of transmission of these microorganisms.[610] There are three types of Transmission-Based Precautions: Airborne, Droplet, and Contact Precautions (see Table 243-2).

Airborne Precautions are designed to prevent transmission of microorganisms spread by droplet nuclei (e.g., measles, varicella, tuberculosis), which can be carried on air currents over substantial distances.[610] Special air handling and ventilation are required.[610]

Droplet Precautions are designed to prevent transmission of microorganisms spread by large respiratory droplets that only travel short distances before settling.[610] Special air handling and ventilation are not required.

Contact Precautions are designed to prevent transmission of microorganisms spread by direct and indirect contact.[610] Some infections are spread by more than one mode of transmission, so precautions systems may need to be combined for these infections (i.e., varicella requires Airborne Precautions and Contact Precautions).

Patients infected or colonized with more than one microorganism also may require a combination of precautions systems (i.e., a patient with active pulmonary tuberculosis and *C. difficile* enterocolitis requires both Airborne Precautions and Contact Precautions).

The HICPAC guideline lists clinical syndromes and conditions warranting empirical use of Transmission-Based Precautions, in addition to Standard Precautions, to prevent transmission of epidemiologically important pathogens until infection with these microorganisms is excluded.[609] To ensure that appropriate empirical precautions are implemented promptly, hospitals must have systems in place to evaluate patients for these infections as a part of their routine preadmission and admission care.

Visitors

Visitors with communicable diseases can inadvertently expose hospitalized patients and health care workers unless procedures to identify and exclude them are in place. Varicella, measles, and tuberculosis are the most problematic infections because these diseases are spread by airborne transmission, enabling infected visitors to expose a large number of individuals in a short time period. In addition, visitors with pertussis, viral respiratory and gastrointestinal infections, parvovirus B19 infection, rubella, and mumps can pose a significant hazard to patients and health care workers with whom they have close contact.

Procedures to identify potentially infected visitors should include visiting children since they are the most likely persons to be infected with these agents. Adult visitors and parents or guardians of visiting children should be asked a set of screening questions regarding the presence of fever, rash, and respiratory and gastrointestinal symptoms, as well as any recent exposure to other children with chickenpox, measles, or whooping cough. Persons without any significant symptoms or exposures should be allowed to visit with no restrictions. Persons who are otherwise well but have a history of a recent minor illness may be allowed to visit but potentially with restrictions, such as no visits by child visitors to the activity room and no sharing of food, drinks, or toys. Persons with fever, symptoms consistent with active respiratory or gastrointestinal infections, or rash consistent with a viral exanthem should not be allowed to visit. Persons with significant exposures to chickenpox or measles who are susceptible to these infections and persons with exposure to pertussis who may be in the incubation period of the disease should also not be allowed to visit. This screening process should be repeated each day that the person visits the hospital. This procedure does not guarantee that persons may not be in the incubation phase of a contagious disease at the time of their visit (varicella is an obvious example) but can be useful in limiting potential exposures.

Occupational Health

Health care workers require protection from the significant infectious risks inherent in patient care; conversely, patients and other health care workers need to be protected from exposure to health care workers with communicable diseases. Integrating management and prevention strategies to accomplish these two goals requires close collaboration between hospital infection prevention and control programs and employee health departments. A HICPAC guideline for infection control in health care workers contains comprehensive recommendations for evaluation of illnesses, postexposure evaluation and management, and prevention of occupationally-acquired infections in health care workers.[69]

Evaluation of Ill Health Care Workers

Hospital staff and volunteers with symptoms such as persistent fever, conjunctivitis, skin lesions or rashes, diarrhea, and persistent cough should be evaluated for the presence of a communicable disease. Possible cases of varicella, herpes zoster on an exposed area of the body, herpetic whitlow, adenoviral conjunctivitis, measles, mumps, rubella, pertussis, staphylococcal skin infection, enteric infection in a food service worker, and active pulmonary tuberculosis should be investigated promptly and confirmed with laboratory tests if necessary. Although many health care workers will choose to have these problems evaluated by their primary care provider, employee health departments have an interest in completing these assessments, especially if there is a question of whether the condition was acquired in the workplace, requires a furlough from work, or may have exposed patients or other health care workers. Infection prevention and control staff members can provide assistance in these evaluations as needed and should be kept abreast of the results.

Postexposure Evaluation and Management of Health Care Workers

A structured approach to the assessment and management of exposures of health care workers to patients with infectious diseases is critical to promptly provide postexposure prophylaxis, if indicated, and allay anxiety, while avoiding unnecessary interventions and loss of workdays. The first step is to develop criteria for assessing the nature of the exposure, because many reported encounters do not pose a significant risk for infection. Some exposures (e.g., varicella, hepatitis B) may require an assessment of the susceptibility of the health care worker to infection, and procedures should describe the indications for laboratory tests as well as the interpretation of results. Postexposure prophylaxis regimens for various exposures are discussed in a HICPAC guideline,[69] and those for bloodborne infections are available in various other guidelines.[109,510] Additional information for postexposure prophylaxis can be obtained by searching the Centers for Disease Control and Prevention website.* Counseling regarding the risks and consequences of the exposure is an important component of this service.

Prevention of Occupationally-Acquired Infections in Health Care Workers

Because vaccination against infectious diseases is a highly cost-effective prevention strategy, hospitals should offer vaccinations free of charge. Vaccination against measles is so effective that ensuring immunity to measles (either as the result of immunity or vaccination) among hospital staff is widely regarded as an appropriate quality of care indicator for occupational health programs.[357] Because the MMR vaccine is readily available, immunity against mumps and rubella can be ensured in an analogous fashion.

Yearly influenza vaccination of health care workers is recommended by the Immunization Practices Advisory Committee, although vaccination rates of health care workers are suboptimal.[121] Interventions to improve vaccination rates are provision of vaccine free of charge, enhanced access to vaccination, reminders and/or incentives, active management of the vaccination program, requiring active declination, and mandatory immunization policies.[296] Mandatory immunization policies are most effective[327,450]; however, despite endorsement by the American Academy of Pediatrics,[55] SHEA,[650] IDSA, and the National Patient Safety Foundation, the approach remains controversial.[327]

Given the significant occupational risk for hepatitis B infection in hospitals, hepatitis B vaccination should be offered routinely to health care workers. The OSHA bloodborne pathogens standard requires hospitals to offer hepatitis B vaccination free of charge; workers who do not wish to be vaccinated must sign a specific "informed refusal." Other vaccines, such as the varicella vaccine and acellular pertussis vaccine, can help eliminate or at least drastically reduce occupational acquisition of these diseases as well.

In addition to hepatitis B vaccination, the OSHA bloodborne pathogens standard mandates other specific prevention measures, including (1) the development of an exposure control plan that identifies employees with occupational risk for exposure to bloodborne pathogens; (2) annual training for these individuals regarding the risk for bloodborne infection and prevention measures; (3) provision of personal protective clothing and equipment; (4) work practice controls, including equipment and procedures for the safe handling and disposal of needles and sharp instruments; and (5) procedures for identification, transportation, storage, and disposal of contaminated items and waste.[498]

The CDC has also published a detailed guideline for prevention and control measures to prevent transmission of *M. tuberculosis* to health care workers.[323]

Reprocessing of Reusable Patient Care Items

A large number of health care–associated infection outbreaks have been related to use of contaminated equipment. Consequently, hospital infection prevention and control programs must work closely with all hospital departments reprocessing reusable patient care items to ensure proper selection, implementation, and quality monitoring of reprocessing methods.[567]

Education and Training of Heath Care Workers

Providing education and training in both general principles and specific aspects of hospital infection prevention and control is one of the primary responsibilities of program staff. Staff members need to be familiar with principles of adult learning, assessing the educational needs of the audience, defining learning objectives,

*Centers for Disease Control and Prevention: http://www.cdc.gov.

determining optimal instructional formats, using effective teaching and communication skills, and weighing the merits of various educational tools.

Product Evaluation

A large number of new medical products are introduced to the health care market every year. Although some of these products have the potential to reduce infectious risks, data to substantiate the safety and efficacy claims of manufacturers often are limited. Many devices marketed to hospitals caring for children have never actually been tested in children. Because these products often are substantially more expensive than existing products there must be a compelling rationale for their use. Infection prevention and control staff members can provide valuable assistance to hospital committees assessing the potential benefits of new products and, when appropriate, can design and conduct appropriate product evaluations trials.

ANTIMICROBIAL STEWARDSHIP PROGRAMS IN HEALTH CARE FACILITIES

The rapid emergence of pathogens resistant to multiple antimicrobial agents (e.g., VRE, ESBL-producing gram-negative bacteria), and the widespread dissemination of these resistant microorganisms, constitute an unprecedented crisis for hospitals worldwide.[73] The mechanisms involved in the emergence and spread of antimicrobial resistance are complex but are no doubt facilitated by intense selective pressure caused by overuse and misuse of antimicrobial agents in hospitals, particularly newer, broad-spectrum agents.

Data from a handful of studies demonstrate that a sizable proportion of hospitalized children—indeed, a substantial majority in some settings, such as ICUs and transplant units—receive empirical, targeted or prophylactic treatment with antimicrobial agents.[245,258,388,509] In one multicenter study, hospitals that used higher volumes of antimicrobial agents were also more likely to use broad-spectrum agents.[245] In another, use of carbapenems had increased substantially from 2002 to 2007.[509] Two studies have examined the appropriateness of therapy and found that inappropriate use of antimicrobial agents is common.[388,515]

In 2007, IDSA and SHEA collaborated to publish a guideline for institutional antimicrobial stewardship programs.[175] Although the guideline found substantial evidence that interventions to improve antimicrobial use decreased costs and improved patient safety (i.e., by reducing errors in prescription of agents to patients with allergies and improving appropriate dosing), the evidence that interventions were effective in improving patient outcomes or controlling antimicrobial resistance was relatively weak. Nonetheless, for the reasons just noted, the rationale for enhanced efforts to improve antimicrobial stewardship remains strong and a survey of infectious diseases specialists participating in the Emerging Infection Network (EIN) indicated that a majority of U.S. facilities have or are planning to establish an antimicrobial stewardship program, although financial support for these programs remains a key barrier.[325] An earlier EIN survey of pediatric infectious diseases specialists yielded similar findings.[289]

In 2012, the IDSA, SHEA, and the Pediatric Infectious Diseases Society (PIDS) collaborated to publish a policy statement on antimicrobial stewardship.[627] The recommendations contained in the statement, which are summarized in Table 243-11, address the leadership and composition of antimicrobial stewardship programs, the activities of these programs, and suggested evaluation approaches. More detail is presented in a recent review of antimicrobial stewardship in health care facilities providing care to children.[480] In addition, a growing literature is expanding the evidence base for interventions to improve antimicrobial stewardship in general and for specific antimicrobial agents that are used commonly (e.g., vancomycin).*

TABLE 243-11 **Minimum Requirements for Antimicrobial Stewardship Programs**

Recommendation
Leadership and composition of program:
Create a multidisciplinary interprofessional team with training in antimicrobial stewardship that includes a physician, a pharmacist, a clinical microbiologist, and an infection preventionist.
Antimicrobial stewardship activities:
Limit the formulary to include nonduplicative antibiotics with demonstrated clinical need.
Develop institutional guidelines for the management of common infection syndromes.
Provide prescribers with a facility-specific antibiogram indicating the rates of relevant antibiotic susceptibilities for key pathogens.
Implement interventions to reduce use of multidrug regimens with unnecessarily redundant antimicrobial spectra, antibiotic therapy for the management of nonbacterial syndromes or cultures that represent contamination or routine colonization, empiric regimens that are either inadequately or excessively broad spectrum for infection syndromes, regimens that do not adequately treat infections caused by culture-confirmed pathogens.
Evaluation
Monitor antimicrobial use at the institutional level for internal and external benchmarking and to gauge the effect of interventions to improve antimicrobial use.

Adapted from Society for Healthcare Epidemiology of America; Infectious Diseases Society of America; Pediatric Infectious Diseases Society. CHAPTER 244

Active Immunizing Agents

Penelope H. Dennehy • Ian C. Michelow • Michael P. Koster • Nicole E. Alexander-Scott

Prevention of infectious diseases in children by immunization is one of the outstanding accomplishments of medical science. Children enjoy better health today because of effective immunization programs, which in many countries have markedly diminished the morbidity and mortality of once common contagious diseases. The striking decline in the United States in vaccine-preventable childhood diseases is demonstrated in Table 244-1.[166,311] Immunization programs have led to the global eradication of smallpox, elimination of measles and poliomyelitis in regions of the world, and substantial reductions in the morbidity and mortality attributed to diphtheria, tetanus, and pertussis.[187] The World Health Organization (WHO) estimated that 2 million child deaths were prevented by vaccinations in 2003.

To achieve this progress in child health, scientific technology and medical practice have combined efforts to (1) understand the biology of causal infectious agents, (2) purify these agents and in some cases their components, (3) develop and test safe and effective vaccines, (4) manufacture and administer these vaccines to appropriate segments of the population, (5) develop appropriate indications and implement schedules for immunizations, and (6) identify necessary contraindications.

Infectious diseases can be prevented through immunization by the following means: (1) stimulating an active immunologic defense (e.g., from humoral antibody) through the administration of antigens, usually before natural exposure to an infectious agent (i.e., active immunization), or (2) temporarily supplying preformed human or animal antibody to persons before or soon after exposure to certain infectious agents (i.e., passive immunization). Active immunizations, including the currently available vaccines, are discussed in this chapter. Major vaccines (i.e., those discussed in this chapter) and their composition and routes of administration are listed in Table 244-2.

ACTIVE IMMUNOPROPHYLAXIS: CONSIDERATIONS AND RECOMMENDATIONS

Vaccines

An ideal immunizing agent should include the following characteristics: (1) the agent should be easy to produce in well-standardized preparations that are readily quantifiable and stable in immunobiologic potency, (2) it should be easy to administer, (3) it should not produce disease in the recipient or susceptible contacts, (4) it should induce long-lasting (ideally permanent) immunity that is measurable by available and inexpensive techniques, (5) it should be free of contaminating and potentially toxic substances, and (6) adverse reactions should be minimal and minor in consequence. All these objectives rarely, if ever, are met with the currently available vaccines because they are neither completely safe nor completely effective. Partial immunity or undesirable side effects or reactions, or both, including rare severe reactions, can occur. Nonetheless, vaccines in current use are highly effective and very safe.

All active immunizing agents (vaccines) contain one or more antigens that stimulate a protective immunologic response. Some are live attenuated viruses or bacteria; other vaccines consist of killed microorganisms or contain inactivated components such as exotoxins (i.e., toxoids). In some vaccines, the antigen is a highly defined, single constituent, such as *Haemophilus influenzae* type b polysaccharide, whereas in others the antigen component is less well defined (e.g., live viruses or whole-cell pertussis vaccines composed of killed *Bordetella pertussis* organisms). Immunizing agents are administered in suspending fluids such as sterile water, saline solution, or complex tissue culture fluid that can contain proteins or other constituents derived from the medium from which the vaccine was produced (e.g., serum proteins, egg antigens, or other tissue culture–derived antigens). With some vaccines, certain preservatives, stabilizers, or antibiotics are added; in some cases, these additives can result in hypersensitivity reactions. To enhance immunogenicity, particularly for vaccines containing inactivated microorganisms or their extracted components, adjuvants such as aluminum compounds may be added.

Immunization Schedules

The age and timing of immunization are critical for the success of vaccination. The schedule by which a vaccine is provided is based on multiple factors, including the epidemiology of naturally occurring disease, the age-specific risk for complications caused by the natural disease, the anticipated immunologic response of the host to the antigens, the duration of immunity that can be induced, and, often, the recommended ages for routine health care visits. In general, vaccines are recommended at the youngest age at which significant risk for the natural disease and its complications exist and at which a protective immunologic response to the vaccine will occur. An example is measles vaccine, which in the United

TABLE 244-1 Reduction in Morbidity of Some Vaccine-Preventable Diseases in the United States

	Maximum Cases (Yr)	2011	Percent Decrease (%)
Diphtheria	206,939 (1921)	0	100
Pertussis	265,269 (1934)	18,719	93

TABLE 244-2 Available Vaccines in the United States for Use in Children and Their Routes of Administration*

Vaccine	Type	Recommended Route
BCG	Live bacteria	ID (preferred) or SC
Diphtheria-tetanus (DT, Td)	Toxoids	IM
DTaP	Toxoids and inactivated bacterial components	IM
DTaP-hepatitis B- IPV (combination)	See DTaP, hepatitis B, and IPV	IM
DTaP-IPV/Hib (combination)	See DTaP, IPV, and Hib	IM
DTaP-IPV (combination)	See DTaP and IPV	IM
Hepatitis A	Inactivated virus	IM
Hepatitis B	Recombinant viral antigen	IM
Hepatitis A- hepatitis B (combination)	See hepatitis A and hepatitis B	IM
Hib	Bacterial polysaccharide-protein conjugate	IM
Hib-hepatitis B (combination)	See Hib and hepatitis B	IM
Human papilloma virus (HPV2 and HPV4)	Recombinant viral antigens	IM
Influenza (TIV)	Inactivated viral components	IM
Influenza (LAIV)	Live-attenuated viruses	Intranasal
Japanese encephalitis	Inactivated virus	SC
Meningococcal polysaccharide (MPSV4)	Bacterial polysaccharide	SC
Meningococcal conjugate (MCV4)	Bacterial polysaccharide-protein conjugate	IM
MenCY-Hib (combination)	Bacterial polysaccharide-protein conjugates	
MMR	Live-attenuated viruses	SC
MMRV	Live-attenuated viruses	SC
Pneumococcal polysaccharide (PPSV)	Bacterial polysaccharide	IM or SC
Pneumococcal conjugate (PCV13)	Bacterial polysaccharide-protein conjugate	IM
Poliovirus (IPV)	Inactivated viruses	SC
Rabies	Inactivated virus	IM
Rotavirus (RV1 and RV5)	Live-attenuated viruses	oral
Tdap	Toxoids and inactivated bacterial components	IM
Typhoid	Bacterial capsular polysaccharide	IM
Typhoid	Live-attenuated bacteria	Oral
Varicella	Live-attenuated virus	SC
Yellow fever	Live-attenuated virus	SC

*Only major childhood vaccines and selective others are included.

BCG, bacille Calmette-Guérin (tuberculosis); DT, diphtheria-tetanus toxoids (for children <7 yr); DTaP, diphtheria-tetanus toxoids–acellular pertussis vaccine (for children <7 yr); Hib, *Haemophilus influenzae* type b conjugate vaccine; ID, intradermal; IM, intramuscular; IPV, inactivated poliovirus vaccine; MMR, live measles-mumps-rubella viruses vaccine; MMRV, live measles-mumps-rubella-varicella viruses vaccine; SC, subcutaneous; Td, tetanus-diphtheria toxoid (for children ≥7 yr and adults); Tdap, diphtheria–reduced tetanus toxoids–acellular pertussis vaccine (for children ≥10 yr and adults).

States is recommended routinely at 12 to 15 months of age because many children have residual, transplacentally acquired maternal measles serum antibody in the first year of life that will interfere with the antibody response. However, during measles outbreaks or for travel of infants to measles endemic areas, measles vaccination is recommended for infants as young as 6 months because the risk for complications with measles is high in children younger than 1 year.[20,133] These infants should be vaccinated again at 12 to 15 months of age. Similarly, in countries where measles causes significant morbidity and mortality in infants younger than 9 months, the Global Advisory Group of the WHO's Expanded Programme on Immunization (EPI) has recommended giving measles vaccine to infants as young as 6 months.[293]

The recommended doses of vaccine are determined by the number necessary to achieve a uniform and predictable immunologic response and to sustain protection. Some immunizing agents require the administration of more than one dose for development of an adequate antibody response and require a booster dose to maintain protection; examples are pertussis, diphtheria, and tetanus vaccines. Intervals between doses are based on the kinetics of primary and secondary antibody responses.

Route of Administration

An example of the effect of the route of administration on immunologic response is provided by poliomyelitis vaccines. Inactivated poliovirus vaccines given intramuscularly induce systemic immunity through serum antibody production; however, they do not consistently evoke local secretory immunoglobulin A (IgA) antibodies in the intestinal tract and thereby effectively prevent subsequent transmission of wild-type virus. Because live attenuated oral polio vaccine (OPV) induces optimal intestinal as well as systemic antibody, it was the preferred vaccine for routine immunization of children in the United States against poliomyelitis for 3 decades and remains the recommended vaccine by the WHO for global eradication.[503,579] Vaccines containing adjuvants must be injected deep into the muscle mass because if they are administered subcutaneously or intradermally, they can cause local irritation, inflammation, granuloma formation, or necrosis.[9,358]

Injectable vaccines should be administered in areas unlikely to cause local neural, vascular, or tissue injury (Table 244-3).[9,358] Although the upper, outer quadrant of the buttocks has been used as a frequent site of immunization, this area ordinarily should not be used because the gluteal region consists mostly of fat in young children and because of potential injury to the sciatic nerve. Ideally, intramuscular injections should be given in the anterolateral aspect of the upper part of the thigh or the deltoid muscle of the upper part of the arm. The anterolateral aspect of the thigh is preferred for infants because of its muscle mass relative to other sites. For older children, the deltoid muscle usually is sufficiently large for intramuscular injection. The incidence of significant pain in 18-month-old children injected intramuscularly in the thigh is greater than that after deltoid injections and can result in transient limping.[326] The deltoid generally is the preferred site for intramuscular administration of vaccines in children 18 months and older, although some physicians prefer the anterolateral aspect of the thigh for toddlers.[9,358] Subcutaneous inoculations also usually should be given in the thigh of infants and the deltoid area of older children. Intradermal vaccines generally should be administered on the volar aspect of the forearm.

Recommended routes for administration of vaccines are provided in their package inserts and are summarized in recommendations for immunizations by the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP)[9] and the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC).[9]

TABLE 244-3 **Site and Needle Length by Age for Intramuscular Immunization**

Age Group	Needle Length, inches (mm)	Suggested Injection Site
Neonate (preterm and term) and infants <1 mo of age	⅝ (16)	Anterolateral thigh muscle
Term infant, age 1-12 mo	1 (25)	Anterolateral thigh muscle
Toddlers and children	⅝-1 (16-25)	Deltoid muscle of the arm
	1-1¼ (25-32)	Anterolateral thigh muscle
Adolescents and young adults		
Female and male, <60 kg	1 (25)	Deltoid muscle of the arm
Female, 60-70 kg	1 (25)	Deltoid muscle of the arm
Female, 70-90 kg	1 (25)-1½ (38)	Deltoid muscle of the arm
Female, >90 kg	1½ (38)	Deltoid muscle of the arm
Male, 70-118 kg	1 (25)-1½ (38)	Deltoid muscle of the arm
Male, >118 kg	1½ (38)	Deltoid muscle of the arm

Modified from American Academy of Pediatrics. Active immunization. In: Pickering LK, Baker CJ, Kimberlin DW, et al, editors. *Red book: 2012 report of the Committee on Infectious Diseases.* 29th ed. Elk Grove Village, Ill.: American Academy of Pediatrics; 2012, p. 1-56.

Vaccine Dose

The recommended dose of each immunizing agent is derived from theoretical considerations and vaccine trials. Because inactivated immunizing agents cannot replicate in the host, these vaccines must contain an adequate antigenic mass to stimulate the desired immunologic response. Long-lasting immunity with such vaccines requires repeated doses. Exceeding the recommended dose can be hazardous because of excessive local or systemic concentrations of immunizing agents, whereas administration of doses smaller than those recommended may result in inadequate response and protection.[9,358]

Lapsed Immunizations

In general, intervals between multiple doses of an antigen longer than those recommended do not affect the antibody responses achieved, provided the immunization series is completed. Thus, restarting the series after interruption of the vaccine schedule or giving additional doses is not necessary.

Simultaneous Administration of Multiple Vaccines

Because most vaccines can be given simultaneously without impairment of effectiveness or safety, multiple vaccines are given to children concurrently.[348] Simultaneous administration of vaccines is particularly important for inadequately immunized children whose return for further immunization is doubtful or for patients with imminent travel plans. An inactivated vaccine and a live virus vaccine can be administered simultaneously at different sites without interference with the immune response. Exceptions are yellow fever and cholera vaccines because if they are administered simultaneously, antibody responses are diminished. If possible, administration of these vaccines should be separated by at least an interval of 3 weeks.[358]

In the case of live virus vaccines, the immune response to one live virus vaccine can be impaired if it is given within 4 weeks of another.[164,358] Thus, parenteral live virus vaccines not administered on the same day should be given at least 4 weeks apart. This consideration is the basis of the recommended minimal interval of 1 month (defined as 4 weeks) between doses of measles vaccine, such as would be the case for a previously unimmunized person who is entering college. Guidelines for spacing live and killed antigen vaccines are given in Table 244-4.

TABLE 244-4 Guidelines for Spacing the Administration of Live and Inactivated Antigens

Antigen Combination	Recommended Minimum Interval Between Doses
Two or more inactivated*	None; may be administered simultaneously or at any interval between doses
Inactivated plus live	None; may be administered simultaneously or at any interval between doses
Two or more live parenteral†	28-day minimum interval if not administered simultaneously

*If simultaneous administration of diphtheria–reduced tetanus toxoids–acellular pertussis vaccine (Tdap) and meningococcal polysaccharide–protein conjugate vaccine (MCV4) is not feasible (i.e., a vaccine is not available), the vaccines should be separated by at least 28 days.

†Some live oral vaccines (e.g., Ty21a typhoid vaccine, oral poliovirus vaccine, rotavirus vaccine) can be administered simultaneously or at any interval before or after inactivated or live parenteral vaccines.

Record Keeping, Patient Information, Informed Consent, and Reporting

Accurate record keeping by physicians is required, and parents (or patients) should keep up-to-date immunization records for their children. The 1986 National Childhood Vaccine Injury Act (NCVIA) requires that for routinely recommended childhood vaccines, health care providers record in the child's permanent medical record the date of administration of the vaccine, manufacturer, lot number, and the name of the health care provider administering the vaccines.[9]

As a general principle, all children and their parents or caregivers should be informed about the benefits and risks of any vaccines to be administered. For vaccines currently specified in the NCVIA, Vaccine Information Statements (VISs) have been prepared by the CDC and must be used by vaccine administrators.

Informed consent should be obtained before the administration of vaccines. Some physicians and other health care providers may choose to obtain the parent's signature, but current law does not require written consent. An appropriate alternative to written consent is to note in the patient's record that the VISs have been provided and discussed with the parent, patient, or legal guardian.[9]

To increase knowledge about adverse reactions, all temporally associated events severe enough to require the patient to seek medical attention should be reported to the Vaccine Adverse Events Reporting System (VAERS).* Health care providers who administer vaccines are required in the United States to report to the VAERS specific adverse events in recipients of the vaccines covered by the NCVIA.† This system for reporting adverse events associated with vaccination was established by the U.S. Department of Health and Human Services to foster recognition of vaccine-related reactions and further study, as indicated, to establish possible causation.

The decrease in the occurrence of vaccine-preventable infectious diseases has resulted in a greater number of adverse events temporally related to immunization than cases of disease. Although in some cases, such as vaccine-associated paralytic poliomyelitis, vaccine has been established to be the cause; in other circumstances, such as brain damage alleged to be attributed to whole-cell pertussis vaccine, causation by vaccine has not been proved.[47]

Increased public visibility of vaccine reactions contributed to a marked increase in vaccine litigation in the 1980s as compensation was sought through the judicial system by those alleged to have suffered serious vaccine-related sequelae. A marked increase in manufacturers' actual and anticipated liability costs and subsequent escalating increases in the price of vaccines occurred concomitantly. These and other developments, such as threats to the vaccine supply, concerns by parents about

*VAERS forms can be obtained by calling 800-822-7967 or by accessing the web site at http://vaers.hhs.gov.

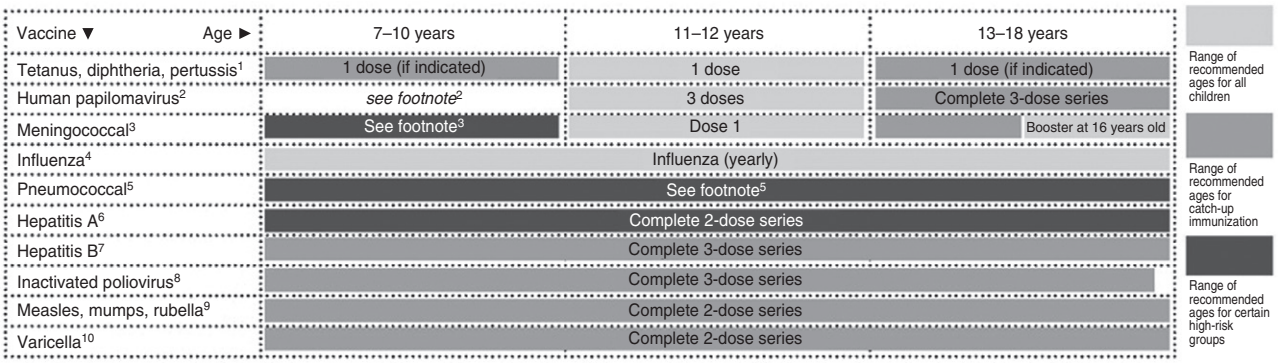

FIGURE 244-2 ■ Recommended immunization schedule for persons aged 10 to 18 years: United States. (From Centers for Disease Control and Prevention. *Immunization schedules.* Available at http://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html.)

vaccine safety, and recognition of the benefits derived from improved coordination and planning of vaccine programs, led to passage of the 1986 NCVIA and the National Vaccine Injury Compensation Program, a no-fault system to compensate victims of certain presumed vaccine-related events.

The Department of Health and Human Services administers the compensation program. Decisions on compensation are made by the U.S. Court of Federal Claims and are based on the Vaccine Injury Table, which was revised since passage of the original legislation in response to new findings and analysis by the several Institute of Medicine (IOM) committees. Compensation for injuries occurring after the program's effective date of October 1, 1988, is provided by excise taxes on each vaccine. The program has been successful in reducing vaccine-related litigation, stabilizing vaccine prices, and creating a favorable environment for the introduction of new vaccines.[252]

Vaccine Recommendations and Schedules

In developing recommendations for immunization, multiple factors are considered and include the vaccine's characteristics, scientific knowledge about the principles of immunization, assessment of the benefits of the vaccine, the risk for development of the disease and its complications, vaccine costs, and the risk for having adverse reactions. Changes in relative benefits and risks necessitate continued review of recommendations. In the United States, recommendations for immunization of infants and children are made by two different committees, the ACIP of the CDC and the AAP Committee on Infectious Diseases. These committees work closely together, and, in most circumstances, their recommendations are similar. These two committees and the American Academy of Family Practice (AAFP) issue a single vaccine schedule each year. The 2012 schedule for routine administration of childhood vaccines is given in Figures 244-1 through 244-3.

A major change in 1996 was the establishment of a routine preadolescent immunization visit at 11 to 12 years of age.[124] The dose of adult tetanus-diphtheria-acellular pertussis (Tdap) vaccine should be given at that time, as should a dose of the meningococcal conjugate vaccine and the first dose of human papillomavirus (HPV) vaccine.[159] In addition, at this preadolescent visit, children not previously vaccinated with hepatitis B, varicella, or the second dose of measles-containing vaccine (or any combination of these vaccines) should be given the necessary immunizations and scheduled for future visits to receive any vaccines not administered during this visit.

Other countries have similar national mechanisms for formulating immunization schedules and recommendations that are based on the local epidemiology of diseases

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to dose 2	Dose 2 to dose 3	Dose 3 to dose 4	Dose 4 to dose 5
Persons aged 4 months through 6 years					
Hepatitis B	Birth	4 weeks	8 weeks and at least 16 weeks after first dose; minimum age for the final dose is 24 weeks		
Rotavirus[1]	6 weeks	4 weeks	4 weeks[1]		
Diphtheria, tetanus, pertussis[2]	6 weeks	4 weeks	4 weeks	6 months	6 months[2]
Haemophilus influenzae type b[3]	6 weeks	4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose) if first dose administered at age 12–14 months No further doses needed if first dose administered at age 15 months or older	4 weeks[3] if current age is younger than 12 months 8 weeks (as final dose)[3] if current age is 12 months or older and first dose administered at younger than age 12 months and second dose administered at younger than 15 months No further doses needed if previous dose administered at age 15 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months	
Pneumococcal[4]	6 weeks	4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose for healthy children) if first dose administered at age 12 months or older or current age 24 through 59 months No further doses needed for healthy children if first dose administered at age 24 months or older	4 weeks if current age is younger than 12 months 8 weeks (as final dose for healthy children) if current age is 12 months or older No further doses needed for healthy children if previous dose administered at age 24 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age	
Inactivated poliovirus[5]	6 weeks	4 weeks	4 weeks	6 months[5] minimum age 4 years for final dose	
Meningococcal[6]	9 months	8 weeks[6]			
Measles, mumps, rubella[7]	12 months	4 weeks			
Varicella[8]	12 months	3 months			
Hepatitis A	12 months	6 months			
Persons aged 7 through 6 years					
Tetanus, diphtheria/tetanus, diphtheria, pertussis[9]	7 years[9]	4 weeks	4 weeks if first dose administered at younger than 12 months 6 months if first dose administered at 12 months or older	6 months if first dose administered at younger than age 12 months	
Human papiliomavirus[10]	9 years	Routine dosing intervals are recommended[10]			
Hepatitis A	12 months	6 months			
Hepatitis B	Birth	4 weeks	8 weeks (and at least 16 weeks after first dose)		
Inactivated poliovirus[5]	6 weeks	4 weeks	4 weeks[5]	6 months[5]	
Meningococcal[6]	9 months	8 weeks[6]			
Measles, mumps, rubella[7]	12 months	4 weeks			
Varicella[8]	12 months	3 months if person is younger than age 13 years 4 weeks if person is aged 13 years or older			

FIGURE 244-3 ■ Catch-up immunization schedule for persons aged 4 months to 18 years who start late or who are more than 1 month behind. (From Centers for Disease Control and Prevention. *Immunization schedules.* Available at http://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html.)

and available vaccines. In developing countries, practices are guided by the WHO's EPI.[578] Current recommendations are listed in Table 244-5.

As new vaccines and scientific knowledge become available, vaccine recommendations and schedules are modified and changed. Examples of changes in the past decade include the use of pneumococcal conjugate vaccine beginning at 2 months of age, universal toddler hepatitis A immunization, recommendations for administration of a second dose of varicella vaccine, and the introduction of acellular pertussis vaccines for adolescents and adults.

Implementation of Vaccine Programs

In addition to the availability of safe and effective vaccines and appropriate schedules for their use, effective means of implementation and delivery are necessary for the success of vaccine programs. In the United States, high rates of immunization in school-aged children have been achieved, in part because of public health programs for vaccine administration, government support for vaccine purchase, and state laws requiring immunization for school entry. In contrast to rates of approximately 95 percent or higher in school-aged children, immunization rates in infants and young children in the 1980s were significantly lower.[591] In a survey of 21 primarily urban areas throughout the United States, 11 to 58 percent (median, 44%) of children who entered school in 1991 and 1992 were fully vaccinated by their second birthday. Failure to immunize young children was a major factor in the outbreaks of measles in major urban areas in the United States in 1989 through 1991.[525]

This epidemic and the recognition of low immunization rates prompted a national campaign to achieve the U.S. Public Health Service's goal of a 90 percent vaccine coverage rate in children by the time they were 2 years of age. Initiatives have included improved access to vaccines, education of health care providers in the community, and the development of standards for pediatric immunization practice.[432] These standards have been endorsed by the AAP, AAFP, and other major professional organizations and serve as guidelines to be followed for improving the delivery of vaccines. They include evaluation of the immunization status of patients at all medical visits, the use of valid contraindications, simultaneous

6 wk	DTP-1, OPV-1, Hib-1, PCV-1, RV-1	HB-2	HB-2
10 wk	DTP-2, OPV-2, Hib-2, PCV-2, RV-2		HB-3
14 wk	DTP-3, OPV-3, Hib-3, PCV-3, RV-3	HB-3	HB-4
9 mo	Measles, yellow fever‡		

*Modifications may be made by the ministries of health in individual countries on the basis of local conditions.
†Hib vaccines are in use in some developing countries. Vaccines for PCV and RV are not yet used in the national immunization program in most developing countries.
‡In countries where yellow fever poses a risk.
BCG, bacille Calmette-Guérin; DTP, diphtheria–tetanus–whole cell pertussis; HB, hepatitis B; OPV, oral poliovirus; Hib, *Haemophilus influenzae* type b; PCV, pneumococcal conjugate vaccine; RV, rotavirus vaccine.

administration of all indicated vaccines, and routine audit of the immunization status of patients by providers. These and other initiatives have resulted in increasing immunization rates of young children. According to the National Immunization Survey, coverage rates in children 19 to 35 months of age in 2011 were 74 percent for completion of the four doses of tetanus-diphtheria-pertussis/diphtheria-tetanus toxoid-acellular pertussis/diphtheria-tetanus (DTP/DTaP/DT), three of poliovirus vaccine, and one dose of measles-mumps-rubella (MMR) vaccine, three doses of hepatitis B vaccine, one dose of varicella vaccine, and four doses of pneumococcal conjugate vaccine. *H. influenzae* type b vaccine is excluded because of nationwide shortages.[134] Vaccination coverage rates in the United States for preschool-aged children consistently have been greater than 70 percent since 2009.

Vaccine Contraindications, Precautions, and Use in Special Circumstances

Recommendations for the use of specific vaccines include contraindications and use in special circumstances, such as immunocompromised patients (from underlying disease or therapy, such as high-dose corticosteroids) and pregnancy.[18,358] Established, generic contraindications are moderate or severe illness, a previous anaphylactic reaction to the specific vaccine, and a severe hypersensitivity reaction, such as anaphylaxis, to a vaccine constituent.

The decision to defer immunization in a febrile child should be based on the physician's assessment of the severity of the illness rather than the degree of fever. Children with minor illness and low-grade fever generally should be vaccinated, especially if a child is unlikely to return promptly for the deferred immunization.

Administration of live virus vaccines such as varicella and MMR vaccines generally is contraindicated in patients with altered immunity. However, the morbidity and mortality rates of measles and the lack of complications from vaccination of children infected with human immunodeficiency virus (HIV) have led to recommendations that these children, unless significantly immunocompromised, receive the MMR vaccine.[48,132,560]

Because of a theoretical risk to the developing fetus, administration of live virus vaccines in most cases is not recommended for pregnant women.[18,358] However, inadvertent administration of vaccine is not necessarily a reason for termination of the pregnancy, and some live virus vaccines, such as those for yellow fever and poliomyelitis, can be given safely to pregnant women. Inactivated bacterial and viral vaccines such as tetanus toxoids, hepatitis B, and influenza vaccine, which are composed of antigenic components or killed organisms, can and should be given during pregnancy if indicated.

In some recipients, vaccines can cause severe reactions, which may be a contraindication or precaution to subsequent administration of the specific vaccine. An example is a child in whom a fever of 40.5°C (105°F) or higher develops after receiving DTaP vaccine, for whom administration of further doses of pertussis-containing vaccine is not indicated in most cases. This recommendation is based on the unproven but reasonable presumption that children who experience adverse reactions after receiving pertussis immunization are at risk for having similar reactions of equal or greater magnitude on subsequent immunization.[192]

Anaphylactic reactions caused by allergenic components of a vaccine, such as gelatin or egg protein (in vaccine prepared in embryonated chicken eggs), have occurred in rare cases. Vaccines posing a potential risk for egg-sensitive persons include those against measles, mumps, inactivated influenza, and yellow fever. Before administering vaccines to persons with possible hypersensitivity to vaccine constituents, physicians should review current recommendations for these vaccines. In other circumstances, specific immunizations may be contraindicated because of previous reactions and the child's past history, such as with DTaP (e.g., evolving neurologic disorders) and MMR (e.g., immune thrombocytopenia occurring in temporal association with vaccination).[358]

Misconceptions

Appropriate and safe use of vaccines requires knowledge of the patient's relevant medical history, adverse reactions associated with previous receipt of vaccines, and specific indications and contraindications. Without this information, vaccines may be administered inadvertently or not given in circumstances in which immunization is indicated, thereby resulting in missed opportunities for receiving the recommended immunization and susceptibility of the child to a preventable disease. Examples of common misconceptions concerning contraindication to vaccines are given in Table 244-6.

TABLE 244-6 Misconceptions Concerning Vaccine Contraindications

- Mild acute illness with low-grade fever or mild diarrheal illness in an otherwise well child
- Current antimicrobial therapy or the convalescent phase of illness
- Reaction to previous vaccine dose that involved only soreness, redness, or swelling in the immediate vicinity of the vaccination site or temperature of less than 40.5°C (105°F)
- Prematurity. The appropriate age for initiating most immunization in the prematurely born infant is the usual recommended chronologic age. Vaccine doses should not be reduced for preterm infants.
- Pregnancy of mother or other household contact. Vaccine viruses in MMR vaccine are not transmitted by vaccine recipients. Although varicella vaccine and influenza vaccine viruses have been transmitted by a healthy vaccine recipient to contacts, the frequency is rare, only mild or asymptomatic infection has been reported, and use of vaccine is not contraindicated by pregnancy of either the child's mother or other household contacts.
- Recent exposure to an infectious disease
- Breast-feeding. The only vaccine virus that has been isolated from breast milk is rubella vaccine virus. No evidence indicates that breast milk from women immunized against rubella is harmful to infants.
- A history of nonspecific allergies or relatives with allergies
- Allergies to penicillin or any other antibiotic, except anaphylactic reactions to neomycin or streptomycin. These reactions occur rarely, if ever. None of the vaccines licensed in the United States contains penicillin.
- Allergies to duck meat or duck feathers. No vaccine available in the United States is produced in substrates containing duck antigens.
- Family history of convulsions in persons considered for pertussis or measles vaccination
- Family history of sudden infant death syndrome in children considered for DTaP vaccination
- Family history of an adverse event, unrelated to immunosuppression after vaccination
- Malnutrition

DTaP, diphtheria-tetanus-acellular pertussis; MMR, measles-mumps-rubella.

International Travel

Foreign travel often is an indication for giving vaccines not routinely administered to children.[18] The risk for exposure to certain vaccine-preventable diseases may be increased relative to that in the United States, and travelers may be exposed to infections that are uncommon or do not occur in the United States. Examples include vaccines against hepatitis A, typhoid fever, yellow fever, and Japanese encephalitis (JE) (Table 244-7), depending on the location and circumstances of the person's visit. Some countries may require yellow fever vaccination for entry. The second dose of measles vaccine should be given to children and adolescents who have received only one dose (provided 4 weeks or more have elapsed since administration of the first dose), irrespective of age, because the risk for exposure to cases of measles may be substantial in some foreign countries. In addition, children and adolescents should have received all vaccines routinely recommended for their age. Information on vaccine requirements for international travel to different countries is provided in a semiannually revised publication by the CDC entitled *Health Information for International Travel*.[383]* Information also is available from the CDC International Travelers Hotline† or on the Internet at the CDC Traveler's Health website.‡

Vaccine Safety

Immunizations are among the most cost-effective and widely used public health interventions. Public health recommendations for vaccine programs and practices represent a dynamic balancing of risks and benefits. Vaccine safety or monitoring of risk is necessary to weigh this balance accurately and adjust vaccination policies accordingly.

No vaccine is perfectly safe or effective. As the incidence of vaccine-preventable diseases is reduced, public concern refocuses from the risk for contracting disease to the health risks associated with vaccines. A higher standard of safety generally is expected of vaccines than of other medical interventions because, in contrast to most pharmaceutical products that are administered to ill persons for curative purposes, vaccines generally are given to healthy persons to prevent the acquisition of disease. Public tolerance of adverse reactions related to products given to healthy persons, especially healthy infants, is substantially lower than that to products administered to persons who are already ill. This lower tolerance of risk for vaccines necessitates investigating possible causes of rare adverse events after administration of vaccinations more aggressively than would be acceptable for other pharmaceutical products. Because vaccination is such a common event, any health problem that occurs after immunization may be attributed to the vaccine. Health effects reported as being associated with vaccines may be true adverse reactions or may be associated with vaccination only by coincidence. Because a temporal relationship alone does not necessarily indicate causation, cause-and-effect relationships often are impossible to establish. Epidemiologic and related studies must be performed to ascertain the incidence and nature of adverse reactions to vaccines, and such studies are important in ensuring a scientific rationale for recommendations for vaccine use and optimal public and professional acceptance of vaccines.

The topic of vaccine safety became prominent during the mid 1970s with increases in the number of lawsuits filed on behalf of patients presumably injured by the DTP vaccine.[261] Legal decisions were made and damages awarded despite the lack of scientific evidence to support claims of vaccine injury.[261] As a result of the liability, prices soared, and several manufacturers halted production. A shortage of vaccines resulted, and public health

officials became concerned about the return of epidemic diseases. To reduce liability and respond to public health concerns, Congress passed the NCVIA in 1986.

The NCVIA mandates that all health care providers report certain adverse events that occur after the administration of vaccination with routinely recommended childhood vaccines. As a result, VAERS was established by the U.S. Food and Drug Administration (FDA) and the CDC in 1990. VAERS provides a mechanism for the collection and analysis of adverse events associated with vaccines currently licensed in the United States. Adverse events are defined as health effects occurring after immunization that may or may not be related to the vaccine. VAERS data are monitored continually to detect previously unknown adverse events or increases in known adverse events.[191]

The gaps that exist in the scientific knowledge of rare vaccine adverse events prompted the CDC to develop the Vaccine Safety Datalink (VSD) project.[189] This project involved forming partnerships with four large health maintenance organizations to monitor vaccine safety continually. VSD is an example of a large, linked database and includes information on more than 6 million persons. The VSD project allows for planned vaccine safety studies, as well as timely investigations of hypotheses.

In the late 1990s, reports in the lay press questioned the safety of routine immunizations and alarmed parents with unsupported accounts of the dangers of vaccines. One major national television network broadcast a feature piece that linked diabetes to childhood immunizations. In the United Kingdom, a report linked receipt of measles vaccine to the development of autism, and in France, hepatitis vaccine was reported to cause multiple sclerosis (MS).

Vaccination and Diabetes. Classen and Classen suggested that certain vaccines, if given at birth, may decrease the occurrence of type 1 diabetes, whereas if initial vaccination is performed after children are 2 months of age, the occurrence of diabetes increases.[196] Other researchers have not found an increased risk for diabetes associated with vaccination.[319] The Classen theory is based on results from experiments in laboratory animals, as well as comparisons of rates of diabetes among countries with different immunization schedules.[196] Applying findings from laboratory animals to humans is fraught with uncertainties. Comparison of diabetes rates among countries with different vaccination policies also provides weak evidence because many factors, including vaccination schedules, may differ by country. In addition, other factors, including genetic predisposition and numerous possible environmental exposures unrelated to the administration of vaccines, may influence the development of diabetes.[319]

The most rigorous epidemiologic study of infant vaccinations and type 1 diabetes to date found that measles vaccine was associated with a decreased risk and no association was found with bacille Calmette-Guérin (BCG), smallpox, tetanus, pertussis, rubella, or mumps vaccine.[82] In a large clinical trial of the *Haemophilus influenzae* type b (Hib) vaccine conducted in Finland, no statistically significant association was found between the receipt of the vaccine and the development of type 1 diabetes during 10 years of follow-up.[338] The IOM Immunization Safety Committee reviewed the clinical and epidemiologic literature in 2002 and concluded that multiple immunizations do not lead to a risk for development of type 1 diabetes.[319]

Measles Vaccine and Autism. The causes of autism are unknown. Most experts agree, however, that autism is a condition that begins before birth.[478] Genetic factors seem to play a major role in the development of autism. Autism usually is diagnosed in children when they are 18 to 30 months old, shortly after they have received many of the recommended vaccinations. Because of this coincidence in timing, some parents of children with autism believe that an immunization may have caused their child's condition.

A 1998 report published in *The Lancet* of 12 patients who had inflammatory bowel disease and autism raised the hypothesis that a link could exist between the MMR vaccine and autism.[555] The authors of the report speculated that MMR vaccine was the possible cause of bowel problems, with the resultant malabsorption of essential vitamins and nutrients leading to autism.

Epidemiologic studies in both the United States and Great Britain do not support a causal association between MMR vaccine and inflammatory bowel disease,[226,425] nor do epidemiologic studies support a causal association between MMR vaccine (and other measles-containing vaccines) and autism.[233,234] Expert panels convened by both the IOM and the AAP examined the available data on autism and MMR vaccine. Both panels concluded that the available evidence does not support the hypothesis that MMR vaccine causes autism or associated disorders or inflammatory bowel disease.[295,322]

Hepatitis B Vaccine and Multiple Sclerosis. Reports of MS developing after receipt of hepatitis B vaccine led to the concern that immunization with hepatitis B vaccine may precipitate the onset of MS or lead to relapses. Since licensure, the safety of the hepatitis B vaccine has continued to be monitored. The several studies conducted did not find a scientific association between hepatitis B vaccination and the development of severe neurologic adverse events such as optic neuritis and Guillain-Barré syndrome. Two large epidemiologic studies examined the risk for an association between vaccines and MS. The first, a case-control study in a large cohort of nurses, demonstrated no significant association between hepatitis B vaccination and development of MS.[59] A French study of patients with MS found that vaccination did not appear to increase the short-term risk for relapse.[211]

The Immunization Safety Review Committee of the IOM reviewed all available data and issued a report in 2004. The committee concluded that the evidence did not support a causal relationship between hepatitis B vaccine administered to adults and onset or relapse of MS.[324]

Thimerosal-Containing Vaccines and Neurodevelopmental Disorders. Thimerosal is a mercury-containing preservative that has been used as an additive to biologics and vaccines since the 1930s because it is effective in preventing bacterial and fungal contamination, particularly in multidose containers. The FDA Modernization Act of 1997 required a review and assessment of the risk for all mercury-containing pharmaceuticals. Assessment of vaccines led to the recognition that, during the first 6 months of life, some children could be exposed to a cumulative quantity of mercury that exceeds one of the federal guidelines on methylmercury. However, a significant safety margin is incorporated into all the acceptable mercury exposure limits, and no data determined or evidence was found that any harm was caused by the level of exposure with the existing immunization schedules. In addition, the risk posed by exposure to thimerosal, which contains ethylmercury, not methylmercury, on which the federal guidelines were based, is unknown. However, to avoid any potential risk, the Public Health Service, the AAP, and vaccine manufacturers agreed in July 1999 that thimerosal-containing vaccines should be removed as soon as possible. As of March 2001, thimerosal no longer was used as a preservative in any of the pediatric vaccines given to children 6 years old or younger in the United States.[173]

A possible association between thimerosal-containing vaccines and increasing diagnoses of autism and autistic spectrum disorders has been investigated in studies in the United States and elsewhere. The Immunization Safety Review Committee of the IOM reviewed all available data and, in October of 2001, issued a report stating that the evidence is inadequate to accept or reject a causal relationship between exposure to thimerosal-containing vaccines and the neurodevelopmental disorders of autism, attention-deficit/hyperactivity disorder (ADHD), and speech and language delay. In addition, the report concluded that the hypothesis that exposure to thimerosal could be associated with the development of neurodevelopmental disorders, although not established, is biologically plausible.[323] The IOM committee recommended that thimerosal-free DTaP, hepatitis B, and Hib vaccines be used for infants, children, and pregnant women, provided an adequate supply is available.[323]

Since the IOM report, five large studies have compared the risk for autism in children who received vaccines containing thimerosal with that in children who received vaccines without thimerosal.[52,260,306,316,543] The studies found the incidence of autism to be the same in both groups.

Reference Sources

Several comprehensive sources of information about pediatric vaccines are available. The AAP publishes *The Red Book: Report of the Committee on Infectious Diseases* every 3 years. The next edition will be published in

2015. In the interval between editions, the AAP publishes recommendations in its newsletter *AAP News* and subsequently in *Pediatrics*. The ACIP issues vaccine recommendations and relevant information in *Morbidity and Mortality Weekly Report*. Manufacturers provide product information for each vaccine in the FDA-approved package inserts.

VACCINES RECOMMENDED FOR ROUTINE ADMINISTRATION

Diphtheria Toxoid

The introduction of diphtheria toxoid–containing vaccine in the 1940s led to a dramatic reduction in the incidence of diphtheria in the United States. From 1980 through 2004, 57 cases of diphtheria were reported in the United States, an average of 2 to 3 per year.[357] Only 5 cases have been reported since 2000. A confirmed case has not been reported in the United States since 2003.[12] However, diphtheria is still a potentially significant public health problem. Serologic surveys in the United States and England have suggested that many adults are not immune.[213,357,388] Although a study published in 1996 demonstrated that most adults in the United States do have protective concentrations of serum antitoxin,[288] more recent data obtained from a national population-based serosurvey published in 2002 revealed that the prevalence of immunity to diphtheria, as determined by the level of diphtheria antitoxin, progressively decreased from 91 percent among children 6 to 11 years of age to approximately 30 percent in those 60 to 69 years of age.[409] Of the reported cases with known patient age since 1980, 58 percent were in persons 20 years of age or older and 44 percent of cases were among persons 40 years of age or older. Most cases have occurred in unimmunized or inadequately immunized persons. The current age distribution of cases corroborates the finding of inadequate levels of circulating antitoxin in many adults. In addition, adequate immunization has not eliminated the potential for transmission of *Corynebacterium diphtheriae* completely because immunization does not prevent carriage of *C. diphtheriae* in the nasopharynx or on the skin.[86,357]

As a result of inadequate immunity in adults as well as in infants and children, an epidemic of diphtheria occurred in the 1990s throughout the former Soviet Union including Russia, Ukraine, and the central Asian republics, with case-fatality rates ranging from 3 to 23 percent.[262,299] In addition, diphtheria continues to be a significant cause of morbidity and mortality in developing countries,[262] and, therefore, it remains a source of possible exposure during travel to endemic countries. Because humans are the only known reservoir for *C. diphtheriae*, universal immunization with a diphtheria toxoid–containing vaccine is the only effective control measure.

Preparations

Diphtheria toxoid is produced by growing toxigenic *C. diphtheriae* in liquid medium. The filtrate is incubated with formaldehyde to convert toxin to toxoid and then is adsorbed onto an aluminum salt adjuvant.

Diphtheria toxoid is available in combination with DTaP for routine immunization of infants and children younger than 7 years of age and for adolescents and adults aged 11 to 64 years as a single booster (Tdap). Two brands of Tdap are available: Boostrix (approved for persons 10 years of age and older) and Adacel (approved for persons 11 to 64 years of age). DTaP and Tdap vaccines do not contain thimerosal as a preservative. Diphtheria toxoid also is available as a DTaP-inactivated poliovirus (IPV)-hepatitis B combination, a DTaP-inactivated poliovirus (IPV)-Hib conjugate combination, and in combination with tetanus toxoid (DT and Td) alone for use when pertussis vaccination is contraindicated. No diphtheria-only vaccine is available. Hib, pneumococcal, and meningococcal conjugate vaccines containing diphtheria toxoid or CRM_{197} protein, a nontoxic variant of diphtheria toxin, are not substitutes for diphtheria toxoid immunization.[12]

Pediatric formulations (DT and DTaP) contain a similar amount of tetanus toxoid as adult Td, but they contain three to four times as much diphtheria toxoid. The concentration of diphtheria toxoid (D) for children younger than 7 years of age per 0.5 mL intramuscular dose of DTaP or DT vaccine is 6.7 to 25 limit of flocculation units (Lf), depending on the vaccine manufacturer. Vaccines approved for children 7 years or older and adults (Tdap and Td) contain only a fraction of the diphtheria toxoid (d, 2 to 2.5 Lf) because of adverse reactions related to dose and age.[12,86,357]

Immunogenicity

After a primary series of three properly spaced diphtheria toxoid doses in adults or four doses in infants, a protective level of antitoxin (defined as ≥0.1 international unit [IU] of antitoxin/mL) is reached in more than 95 percent of vaccinees. Diphtheria toxoid has been estimated to have a clinical efficacy of 97 percent. Immune response to diphtheria toxoid was measured after administration of each adult Tdap vaccine and compared with that elaborated after Td vaccine. Seroprotective anti-diphtheria levels, defined as a titer of 0.1 IU/mL or more, and booster response rates to diphtheria were determined to be noninferior after administration of Tdap as compared with Td vaccination.[357]

Adverse Events

Other than local reactions of pain and swelling at the site of vaccine injection, immunization does not cause significant adverse events. These local reactions have been attributed to hypersensitivity reactions in response to the pertussis component and are not a contraindication for administration of further vaccination if otherwise indicated.

Regarding adverse reactions reported after administration of Tdap, vaccination with Boostrix was associated with a statistically higher rate of moderate to severe headache compared with Td, and vaccination with Adacel was associated with higher rates of mild injection site pain

and low-grade fever compared with the Td vaccine. No serious adverse events have been reported for Boostrix. There have been two reports of serious adverse events, both characterized as neuropathic reactions, in adults, possibly related to having received Adacel (none reported in adolescents); and in both cases, symptoms resolved completely within several days.[86]

Indications

Primary immunization consists of five doses of diphtheria toxoid, provided as DTaP or as DT if pertussis is contraindicated.[12,86,357] The first three doses are administered routinely to children who are 2, 4, and 6 months of age. A fourth dose is administered 6 to 12 months after the third dose, between 12 to 18 months of age, to maintain adequate antibody concentrations for the ensuing preschool years. For those not immunized in infancy, the initial dose is followed by two doses given 2 and 8 to 14 months later. A single booster dose given when the child is 4 to 6 years of age, before school entry, is indicated unless the preceding dose was given after the fourth birthday. Interruption of the recommended schedule or delay in administering subsequent doses during primary immunization does not reduce immunity or necessitate restarting the series.

In 2005, the FDA licensed two vaccines containing tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis antigens (Tdap) for routine use in adolescents and adults. Tdap is recommended only for a single dose across all age groups, including as a one-time only substitute for the next scheduled or recommended Td booster in those individuals who previously completed their primary vaccination series with DTP or DTaP. The preferred age for Tdap vaccination is 11 to 12 years. Adolescents aged 11 to 18 years who completed their primary series with DTP or DTaP are encouraged to receive Tdap. Based on additional data on the safety of administering Tdap less than 5 years after Td, pertussis vaccination, when indicated, should not be delayed, and Tdap should be administered regardless of interval since the last tetanus or diphtheria toxoid-containing vaccine. Although longer intervals between Td and Tdap could decrease the occurrence of local reactions, the benefits of protection against pertussis outweigh the potential risk for adverse events.[182] Every 10 years thereafter, tetanus booster should be provided by Td. Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis initially should receive Tdap followed by Td for the subsequent two doses at 4 weeks or more and 6 to 12 months following.

No pertussis-containing vaccine has been FDA approved for children between the ages of 7 and 10 years. If pertussis vaccine is not contraindicated, children aged 7 through 10 years who are not fully vaccinated (have not received five doses of DTaP or four doses of DTaP if the fourth dose was administered on or after the fourth birthday) should receive a single dose of Tdap to provide protection against pertussis. If additional doses of tetanus and diphtheria toxoid–containing vaccines are needed for children aged 7 through 10 years, after Tdap vaccine is substituted as the first dose, Td vaccine should be the subsequent two doses at 4 weeks or more and 6 to 12 months following if indicated for the catch-up series.[12,182] Tdap is recommended in this age group because of its reduced antigen content compared with DTaP, resulting in reduced reactogenicity.[182]

After exposure to a case of strongly suspected or proven diphtheria, asymptomatic previously immunized persons should receive a booster of an age-appropriate diphtheria toxoid-containing vaccine if they have not received a booster dose of a diphtheria toxoid-containing vaccine within 5 years. Tdap (in persons 10 years of age and older) is preferred over Td, if the person previously did not receive pertussis booster vaccine.[12] If not previously immunized, carriers should receive age-appropriate diphtheria toxoid–containing vaccine (DTaP [or DT], Tdap, or Td) as soon as identified and should complete the entire series.

Patients recovering from diphtheria infection should be immunized because infection does not confer immunity.

Precautions and Contraindications

The only contraindication to diphtheria toxoid is a history of severe hypersensitivity developing after receipt of a previous vaccine dose. Vaccination with either diphtheria or tetanus toxoid is not known to be associated with an increased risk for having convulsions. Local reactions alone do not preclude continued use.

Haemophilus influenzae Type B Vaccine

Before the introduction of routine infant and childhood vaccination against *Haemophilus influenzae* type b, this pathogen was the major cause of invasive bacterial infections in young children in the United States. It was the most common cause of bacterial meningitis and epiglottitis and a significant cause of septic arthritis, osteomyelitis, septicemia, occult febrile bacteremia, pneumonia, pericarditis, and cellulitis in children younger than 5 years, in whom it caused an estimated 12,000 cases of meningitis and 8,000 additional cases of invasive *H. influenzae* type b disease annually.[201] The cumulative risk for *H. influenzae* type b disease was approximately 1 in every 200 U.S. children in the first 5 years of life, with the peak incidence of *H. influenzae* type b meningitis occurring in infants between 6 and 12 months of age. In high-risk populations, such as American Indians, rates of disease in the absence of immunizations were higher, and a greater proportion of cases of meningitis occurred in the first year of life than in non–high-risk populations.[201,308,567]

In 2006, the WHO estimated that at least 3 million cases of serious disease and approximately 386,000 deaths were attributable to *H. influenzae* type b annually. These figures were substantiated by a systematic study on global burden of disease.[561] As of 2011, 171 of the 193 WHO Member States (89 percent) had adopted the vaccine in their routine immunization programs. As a consequence, invasive *H. influenzae* type b disease has been virtually eliminated in many industrialized countries and its

incidence is dramatically reduced in many parts of the developing world. However, the WHO estimates that only 42 percent of the eligible population is vaccinated against *H. influenzae* type b in developing countries, and only 8 percent in the poorest countries.[426] *H. influenzae* type b remains the most common cause of nonepidemic bacterial meningitis in unvaccinated children younger than 1 year of age. Mortality rates for *H. influenzae* type b meningitis treated with appropriate antibiotics range from 3 to 20 percent, and 30 to 40 percent of survivors suffer severe neurologic sequelae.[582]

Because most cases of *H. influenzae* type b disease occur in infancy, vaccines that induce protection before the age of 6 months are necessary for effective control of *H. influenzae* type b disease. The *H. influenzae* type b polysaccharide capsule is the major virulence factor, and antibodies directed against the polysaccharide antigens are protective. Capsular type b is responsible for more than 90 percent of systemic *H. influenzae* infections. However, purified polysaccharide vaccines induce primarily a T-lymphocyte–independent IgM antibody response that is poorly immunogenic, particularly in children younger than 18 months who lack immunologic memory. Covalent linkage of the purified capsular polysaccharide, polyribosylribitol phosphate (PRP), to a protein carrier creates a conjugate glycoprotein that is T-lymphocyte dependent and elicits protective antibody in infants and young children and significantly greater concentrations of circulating anti-PRP at all ages than does the unconjugated polysaccharide. T-cell–dependent antigens involve helper T-lymphocyte activation of a B-cell humoral antibody response. T-cell–dependent antigens also are able to prime for a booster response.

The introduction of Hib conjugate vaccines in the United States, first in children at least 18 months of age in 1987 and for routine infant immunization in 1991, decreased the incidence of meningitis and bacteremia caused by *H. influenzae* type b dramatically. As of 2000, the incidence of invasive *H. influenzae* type b disease in the United States had decreased by 99 percent since the pre-vaccine era, with an incidence rate of less than 1 case per 100,000 children younger than 5 years old.[149] The remarkably rapid reduction in incidence of disease was partly the result of the ability of the vaccine to reduce asymptomatic nasopharyngeal carriage of the organism, an action that had the indirect effect of reducing exposure and infection in those not immunized (herd immunity).[63,303]

Preparations

Two single-antigen Hib conjugate vaccine products and three combination vaccine products that contain Hib conjugate are available in the United States. All Hib vaccines contain PRP (polyribosyl-ribitol-phosphate), the organism's polysaccharide capsular antigen. The two currently licensed single-antigen Hib conjugate vaccines, PRP-OMP (PedvaxHIB) and PRP-T (ActHIB), are approved for use in early infancy (Table 244-8). Another PRP-T product (Hiberix) is approved only for the booster immunization in children from 15 months to 4 years of age. Each conjugate vaccine is chemically and immunologically unique. Both PRP preparations are composed of the type b PRP antigen conjugated to a protein and differ in the protein carrier, size of the saccharide component, and the chemical linkage. The carrier proteins for PRP-OMP and PRP-T are an outer membrane protein from *Neisseria meningitidis* and tetanus toxoid, respectively. Since July 2000, the entire Hib vaccine supply for the United States has been thimerosal free. The dose of each Hib conjugate vaccine is 0.5 mL, given intramuscularly.

Three licensed combination vaccines containing Hib are as follows: (1) DTaP/PRP-T (TriHIBit), which is the combination of Hib with DTaP approved for the fourth dose only; (2) PRP-OMP/Hep B (Comvax), the bivalent Hib and recombinant hepatitis B virus (HBV) vaccine approved for use in children aged 6 weeks to 15 months who were born to hepatitis B surface antigen (HBsAg)–negative mothers, and (3) DTaP/IPV/PRP-T(Pentacel), which is approved for immunization at 2, 4, 6, and 15 to 18 months of age. In June 2012, a combination conjugate vaccine against *H. influenzae* type b (PRP-T) and meningococcus serogroups C and Y (HibMenCY-TT, MenHibrix) was approved for children 6 weeks to 18 months. Recommendations for use of this vaccine are being considered.

Immunogenicity and Efficacy

Placebo-controlled field trials of Hib conjugate vaccines in infants in the United States demonstrated nearly 100

TABLE 244-8 ***Haemophilus influenzae* Type b Conjugate Vaccines**

Manufacturer	Abbreviation (Trade Name)	Carrier Protein
Merck & Co.	PRP-OMP*(PedvaxHIB)	OMP (an outer-membrane protein complex of *Neisseria meningitidis*)
Sanofi Pasteur	PRP-T† (ActHIB)	Tetanus toxoid
GlaxoSmithKline	PRP-T‡ (Hiberix)	Tetanus toxoid

*PRP-OMP is also available as a combination vaccine with hepatitis B (COMVAX).
†PRP-T may be reconstituted with diphtheria–tetanus–acellular pertussis (DTaP) (Tripedia; Sanofi Pasteur) to form TriHIBit. TriHIBit is approved only for the fourth dose of the DTaP and *Haemophilus influenzae* type b (Hib) series. Other licensed formulations of DTaP have not been approved by the U.S. Food and Drug Administration for reconstitution and may not be used for this purpose. DTaP/IPV/PRP-T (Pentacel) is approved for the primary vaccine series in infants.
‡Hiberix is approved only for the fourth dose of the Hib series.
Modified from Pickering LK, Baker CJ, Kimberlin DW, et al, editors. *Red book: 2012 report of the Committee on Infectious Diseases.* 29th ed. Elk Grove Village, Ill.: American Academy of Pediatrics; 2012.

percent protection and provided the basis for the initial approval of these vaccines for use in this country. In a Navajo population of infants at high risk for acquiring *H. influenzae* type b disease who were vaccinated at 2 and 4 months of age with either PRP-OMP or placebo, vaccine efficacy was 100 percent at 1 year of age and 93 percent in total.[491] Licensure of PRP-T was based on immunogenicity in a three-dose schedule that was comparable to that of the other two products. In addition, an efficacy trial in Great Britain and the lack of cases in trials indicate an efficacy of PRP-T comparable to that of PRP-OMP.[83,491,537] Although the data are limited, some evidence suggests that administration of the first dose of the Hib vaccine before the child reaches the age of 6 weeks may result in immunologic tolerance to the *H. influenzae* type b antigen and reduce the immune response to subsequent doses.[410] A PRP antibody concentration of greater than 0.15 μg/mL is considered to indicate short-term protection; concentrations greater than 1.0 μg/mL 1 month after the completion of primary immunizations are considered to be markers of long-term protective immunity against invasive *H. influenzae* type b disease. Children who have invasive *H. influenzae* type b infection before 24 months of age may remain at risk for another *H. influenzae* type b infection and they should be immunized according to the age-appropriate schedule for unimmunized children.[13] Children who develop invasive disease despite two to three Hib vaccines as well as those with recurrent invasive *H. influenzae* type b warrant an immunologic evaluation. Nontypeable *H. influenzae* lacks a polysaccharide capsule that renders the Hib vaccine ineffective against this cause of acute otitis media (AOM), acute sinusitis, bronchitis, and community-acquired pneumonia.

Adverse Events

Hib vaccines are well tolerated. Local reactions occur in approximately 25 percent of recipients but typically are mild and last less than 24 hours.[228,567] Systemic reactions, such as fever and irritability, are infrequent occurrences. When conjugate vaccines are administered concurrently with DTaP vaccine, the incidence of systemic reactions is similar to that observed when only DTaP is given.[228]

Indications

Routine vaccination against *H. influenzae* type b disease is recommended for all children beginning at approximately 2 months of age.[13,121,155] Four vaccines, PRP-T (ActHIB), PRP-OMP (PedvaxHIB), PRP-OMP/hepatitis B (COMVAX), and DTaP/IPV/PRP-T (Pentacel), are licensed in the United States for use in infants. One of these products, PRP-T, can be given with DTaP (Hiberix), mixed in the same syringe for the fourth dose only.

Two or three doses, depending on the product, given at 2-month intervals (optimal) are indicated by the time that the child is 6 months of age. The recommended age to initiate the primary series is 2 months, with a minimum age of 6 weeks. The minimum interval between doses is 4 weeks, with at least 8 weeks separating the last dose in the primary series and the booster. Excellent immune responses have been achieved when vaccines from different manufacturers have been interchanged in the primary series.[51,76,281] PRP-T and PRP-OMP are considered interchangeable for primary as well as booster vaccinations. If more than a single brand of vaccine is used, the child should receive a three-dose primary series. A final dose of any product, irrespective of the previous vaccines received, is acceptable when the child is 12 to 15 months of age for completion of the Hib vaccine immunization schedule. When feasible, the conjugate vaccine product used for the first dose should be used for subsequent doses in children younger than 12 months.

For children in whom immunization for *H. influenzae* type b infection has not been initiated by the time that they reach 7 months of age, the recommended schedules differ according to the child's age and the choice of conjugate vaccine.[32,121] Previously unimmunized children between 15 and 59 months should be immunized with at least a single dose of any licensed conjugate Hib vaccine. For previously unimmunized children 5 years or older, immunization is indicated only if they have an underlying condition predisposing to *H. influenzae* type b disease, such as asplenia, sickle cell disease, immunoglobulin deficiency, or stem cell transplant, or are immunosuppressed because of chemotherapy or HIV infection. More than one dose may be recommended for this population.[13]

Precautions and Contraindications

Conjugate vaccines that contain either diphtheria toxoid or protein should not be considered as an immunizing agent against diphtheria; no changes in the schedule for administering DTP are recommended. A conjugate vaccine that contains meningococcal protein should not be considered as an immunizing agent against meningococcal disease.

Hepatitis A Vaccine

The occurrence of hepatitis A is highest in developing countries and reflects the primary route of transmission, fecal-oral, person-to-person spread. In the United States, before vaccine became available, hepatitis A was a common infection and caused substantial morbidity with significant associated costs.[175,353] In 1995, the hepatitis A vaccine was licensed by the FDA, and during the decade that followed the rate of hepatitis A infection in the United States dramatically declined, reaching an all-time low of 5683 cases in 2004.[255]

In the pre-vaccine era, the incidence of hepatitis A varied considerably in different populations.[255,516] A shift occurred in the epidemiology of hepatitis A in the United States after the introduction of hepatitis A vaccine. Disease in the United States most commonly occurred in children 5 to 14 years of age.[255] After vaccines were licensed, rates of infection among children declined more rapidly than did rates among adults, thus resulting in similar rates among all age groups. Historically, rates of infection were highest among Alaska Natives and American Indians, and most cases occurred in a small number of states and counties in the western and southwestern

regions of the country. During the decade after vaccine was licensed, age-specific, racial, and geographic disparities narrowed considerably.[255]

Individuals at risk for acquiring hepatitis A infections include close contacts of persons infected with hepatitis A virus (HAV), travelers to developing countries, those who engage in homosexual and bisexual activity, and injecting drug users. However, in approximately 50 percent of reported cases, no risk factor is identified.[14] These infections likely are attributable to fecal-oral spread from asymptomatic contacts. Because children frequently have asymptomatic infections and may shed virus for prolonged periods, they play an important role in transmission of HAV. Children and infants shed virus for longer periods than adults do, as long as several months after the onset of clinical illness. In one study involving adults without an identified source of infection, 52 percent of their households included a child younger than 6 years.[255] Therefore, it has long been recognized that the control and ultimate elimination of hepatitis A by active immunization would be best achieved through universal childhood immunization.[539] However, it was not until 2005 that hepatitis A vaccine was licensed for use in children from 12 to 23 months of age. Before then, it had been restricted to children older than 2 years old and consequently could not be incorporated readily into routine infant vaccinations. In May 2006, the ACIP recommended including hepatitis A vaccine in the routine infant immunization schedule.[255]

Before vaccine was available, community-wide outbreaks, recurring every 3 to 10 years in high-risk communities, accounted for much of the occurrence of hepatitis A infection and disease. Outbreaks among children attending daycare and daycare staff are common occurrences and have been associated with community outbreaks.[292] However, the prevalence of hepatitis A infection in daycare center staff and in children and adolescents who previously attended daycare is not increased, a finding suggesting that infections within daycare settings most commonly reflect transmission within the community that extends to these settings.[292] Transmission of HAV also can occur in institutions for the developmentally disabled and in neonatal intensive care units. Transmissions from hospitalized patients to health care professionals have been reported.[14] In addition to these examples of direct person-to-person transmission, infection can be acquired by the ingestion of contaminated food or water.

Preparations

Both inactivated and attenuated HAV vaccines have been developed.[216] However, only inactivated vaccines are licensed in the United States. Inactivated HAV vaccine is prepared by methods similar to those used for inactivated poliomyelitis vaccine. Virus is propagated in human diploid fibroblast cell cultures, formalin inactivated, and adsorbed to aluminum hydroxide adjuvant. Two inactivated HAV vaccines are licensed in the United States: Havrix (SmithKline Beecham Biologicals) and Vaqta (Merck & Co.). Both Vaqta and Havrix have two formulations, an adult and a pediatric product with different antigen content (Table 244-9). The pediatric formulation is indicated for persons aged 12 months to 18 years of age. The vaccines can be used interchangeably.[89] Limited data indicate that hepatitis A vaccine may be administered simultaneously with other vaccinations.[14] A combination HAV/hepatitis B vaccine (Twinrix) is licensed in the United States for persons 18 years of age and older. All HAV-containing vaccines are administered intramuscularly.

Immunogenicity and Efficacy

Inactivated hepatitis A vaccine is highly immunogenic. After receiving a single dose, 95 percent of children and nearly all adults seroconvert within 1 month.[14,255] After receipt of a second dose in children, seroconversion approximates 100 percent. Hepatitis A vaccine is immunogenic in children younger than 2 years old who do not have passively acquired maternal antibody.[462,531] In two large clinical trials of inactivated hepatitis A vaccine in children older than 2 years, protective efficacy was greater than 90 percent.[318,569] In a double-blind, placebo-controlled, randomized study in Thailand involving approximately 34,000 vaccinees, the protective efficacy against clinical hepatitis A was 94 percent after administration of two doses given 1 month apart; it was 100

percent after subsequent administration of a 12-month booster dose.[318]

Vaccination also has been demonstrated to be effective in controlling outbreaks in communities with high rates of disease.[255] For example, in a New York State community in which HAV is highly endemic in children, a single dose of vaccine was 100 percent effective beginning 3 weeks after immunization in preventing symptomatic disease.[569] Moreover, observations from countries where routine hepatitis A vaccination of infants or children has been implemented suggest a strong herd immunity effect.[219,235] The duration of protection after vaccination is likely to be prolonged. Protective antibody levels of anti-HAV were observed in 99 percent of children evaluated 5 to 6 years after receiving Vaqta.[568] Kinetic models of antibody decline indicate that protective levels of antibody could be present for more than 25 years in adults and up to 20 years in children.[538,540] No data are available currently to determine whether and when children will need a hepatitis A booster vaccine. In an ongoing study designed to address the need for a booster dose, no cases of hepatitis A among children 9 years after initial vaccination have been reported.[570]

Reduced vaccine immunogenicity has been observed in infants with passively acquired anti–hepatitis A antibody who are administered hepatitis A vaccines.[217,373,376] Studies demonstrated that, despite the presence of lower antibody levels in infants born to anti–hepatitis A–positive mothers, most infants with passively acquired antibody had an anamnestic response to a booster dose 1 to 6 years later.[217,254,336] In most infants, maternally acquired anti–hepatitis A antibody declines to undetectable levels by the time the child reaches 12 months of age.[377] Hepatitis A vaccine is highly immunogenic for all infants when administered when they are older than 1 year of age, irrespective of maternal antibody status.[69,217]

Concurrent administration of immune globulin and vaccine inhibits the peak serum antibody concentration achieved but not the rate of seroconversion.[553] Because antibody concentrations reach much higher than protective levels, this inhibition is not considered clinically significant and supports passive-active immunoprophylaxis when indicated.

Adverse Events

Except for rare reports of anaphylaxis and anaphylactoid reaction in adults in Europe and Asia, serious reactions to inactivated HAV vaccine have not been reported.[254] Pain, tenderness, and infection at the injection site can occur.[318]

Indications

HAV immunization is recommended routinely for children 12 through 23 months of age, for persons who are at increased risk for infection, for persons who are at increased risk for severe manifestations of hepatitis A if infected, and for any person who wants to obtain immunity.[14,33,175,184,255]

All children in the United States should receive hepatitis A vaccine routinely according to the licensed two-dose schedule, with the initial dose administered at age 1 year (12 to 23 months) and the second dose 6 to 12 months later. Children who are not immunized by 2 years of age can be immunized at subsequent visits.

In addition, hepatitis A vaccination is recommended routinely for the following persons who are at increased risk for acquiring infection[14,33,255]:

- All susceptible persons traveling to or working in countries that have a high or intermediate hepatitis A endemicity; these persons should be vaccinated or receive immune globulin before departure.[175] HAV vaccine at the age-appropriate dose is preferred to immune globulin. The first dose of HAV vaccine should be administered as soon as travel is considered. One dose of single-antigen vaccine administered at any time before departure can provide adequate protection for most healthy persons. Travelers who are younger than 12 months of age should receive a single dose of immune globulin (0.02 mL/kg), which provides effective protection for up to 3 months.
- Susceptible household members and other close personal contacts (e.g., regular babysitter) of international adoptees newly arriving from countries with high or intermediate hepatitis A endemicity.[43,184] Data from a study conducted at 3 adoption clinics in the United States indicate that 1 to 6 percent of newly arrived international adoptees have acute HAV infection. The risk for HAV infection among close personal contacts of international adoptees is estimated at 106 (range, 90 to 819) per 100,000 household contacts of international adoptees within the first 60 days of their arrival in the United States. Therefore, HAV vaccine should be administered to all previously unvaccinated persons who anticipate close personal contact (e.g., household contact or regular babysitting) with an international adoptee from a country with high or intermediate endemicity during the first 60 days after arrival of the adoptee in the United States. The first dose of the two-dose HAV vaccine series should be administered as soon as adoption is planned, ideally two or more weeks before the arrival of the adoptee.
- Men who have sex with men. Outbreaks of hepatitis A among men who have sex with men have been reported often, including in urban areas in the United States, Canada, and Australia. Therefore, men (adolescents and adults) who have sex with men should be immunized.
- Users of injection and noninjection drugs. Periodic outbreaks among injection and noninjection drug users have been reported in many parts of the United States and in Europe. Adolescents and adults who use illegal drugs should be immunized.
- Patients with clotting-factor disorders. Reported outbreaks of hepatitis A in patients with hemophilia receiving solvent-detergent–treated factor VIII and factor IX concentrates were identified during the 1990s, primarily in Europe, although one case was reported in the United States. Therefore, susceptible patients with chronic clotting disorders who

receive clotting-factor concentrates should be immunized.

- Persons at risk for occupational exposure (e.g., handlers of nonhuman primates and persons working with HAV in a research laboratory setting). Outbreaks of hepatitis A have been reported among persons working with nonhuman primates. These infected primates were born in the wild and were not primates that had been born and raised in captivity. Persons working with HAV-infected primates or with HAV in a research laboratory setting should be immunized.
- Persons with chronic liver disease. Because persons with chronic liver disease are at increased risk for fulminant hepatitis A, susceptible patients with chronic liver disease should be immunized. Susceptible persons who are awaiting or have received liver transplants should be immunized.

Although the ACIP guidelines do not recommend routine vaccination of food handlers, consideration may be given to vaccination of these workers in areas where state and local health authorities or private employers determine that vaccination is cost effective.

Postexposure Prophylaxis

Persons who have been exposed to HAV and previously have not received HAV vaccine should receive a single dose of single-antigen HAV vaccine or immune globulin as soon as possible (see Table 244-10 for prophylaxis guidance and dosages).[175] The efficacy of immune globulin or vaccine for postexposure prophylaxis when administered more than 2 weeks after exposure has not been established. Information about the relative efficacy of vaccine compared with immune globulin postexposure is limited, and no data are available for persons older than 40 years of age or persons with underlying medical conditions.

All previously unimmunized persons with close personal contact with a person with serologically confirmed HAV infection, such as household and sexual contacts, should receive vaccine or immune globulin within 2 weeks after the most recent exposure. Serologic testing of contacts is not recommended, because testing adds unnecessary cost and may delay administration of postexposure prophylaxis.

Outbreaks of HAV infection at child care centers have been recognized since the 1970s, but their frequency has decreased as HAV immunization rates in children have increased and as hepatitis A incidence among children has declined. HAV vaccine or immune globulin should be administered to all previously unimmunized staff members and attendees of child care centers or homes if (1) one or more cases of hepatitis A are recognized in children or staff members or (2) cases are recognized in two or more households of center attendees. In centers that provide care only to children who do not wear diapers, vaccine or immune globulin need be given only to classroom contacts of an index-case patient. When an outbreak occurs (i.e., hepatitis A cases in two or more families), vaccine or immune globulin also should be considered for members of households that have children (center attendees) in diapers. Children and adults with hepatitis A should be excluded from the center until 1 week after onset of illness, until the postexposure prophylaxis program has been completed in the center, or until directed by the health department. Although precise data concerning the onset of protection after postexposure prophylaxis are not available, allowing prophylaxis recipients to return to the child care center setting immediately after receipt of the vaccine or immune globulin dose seems reasonable.

Schoolroom exposure generally does not pose an appreciable risk for infection, and postexposure prophylaxis is not indicated when a single case occurs and the source of infection is outside the school. However, HAV vaccine or immune globulin could be used for unimmunized persons who have close contact with the index patient if transmission within the school setting is documented.

Usually, health care–associated HAV in hospital personnel has occurred through spread from patients with acute HAV infection in whom the diagnosis was not recognized. Careful hygienic practices should be emphasized when a patient with jaundice or known or suspected hepatitis A is admitted to the hospital. When outbreaks occur, HAV vaccine or immune globulin is recommended for persons in close contact with infected patients. There

TABLE 244-10 **Recommendations for Postexposure Immunoprophylaxis of Hepatitis A Virus**

Time Since Exposure	Age of Patient	Recommended Prophylaxis
≤2 wk	<12 mo	IG, 0.02 mL/kg
	12 mo through 40 yr	HAV vaccine*
	≥41 yr	IG, 0.02 mL/kg but HAV vaccine can be used if IG is unavailable
	Persons of any age who are immunocompromised or have chronic liver disease	IG, 0.02 mL/kg
≥2 wk	<12 mo	No prophylaxis
	≥12 mo	No prophylaxis but HAV vaccine may be indicated for ongoing exposure

*Dosage and schedule of HAV vaccine as recommended according to age in Table 244-9.
IG, immune globulin.
Modified from Pickering LK, Baker CJ, Kimberlin DW, et al, editors. *Red book: 2012 report of the Committee on Infectious Diseases.* 29th ed. Elk Grove Village, Ill.: American Academy of Pediatrics; 2012.

is no recommendation for routine preexposure use of HAV vaccine for hospital personnel.

If a food handler is diagnosed with hepatitis A, HAV vaccine or immune globulin should be provided to other food handlers at the same establishment. Food handlers with acute HAV infection should be excluded for 1 week after onset of illness. Because common-source transmission to patrons is unlikely, postexposure prophylaxis with HAV vaccine or immune globulin typically is not indicated but may be considered if the food handler directly handled food during the time when the food handler likely was infectious and had diarrhea or poor hygiene practices and if prophylaxis can be provided within 2 weeks of exposure. Routine HAV immunization of food handlers is not recommended.

Postexposure prophylaxis usually is not recommended, because these outbreaks commonly are recognized too late for prophylaxis to be effective in preventing HAV infection in exposed persons. HAV vaccine or immune globulin can be considered if it can be administered to exposed persons within 2 weeks of an exposure to the HAV-contaminated water or food.

Precautions and Contraindications

Hepatitis A vaccine should not be administered to persons with a hypersensitivity reaction to any of the vaccine components, such as alum or, in the case of Havrix, phenoxyethanol.[33] Safety data in pregnant women are not available, but the risk is considered to be low or nonexistent because the vaccine contains inactivated, purified viral proteins.

Hepatitis B Vaccine

HBV infection is a leading cause of acute hepatitis and a major public health problem of global importance. Its incidence is especially high in many Asian and African countries. Individuals with chronic infection are at risk for the development of chronic hepatitis, cirrhosis, and primary hepatocellular carcinoma. Rates of new infection are highest among adults, but chronic infection is more likely to occur in individuals infected as infants or children. These persons not only are at increased risk for chronic and malignant liver disease but also, as chronic carriers, serve as the reservoir for transmission of HBV.

The initial strategies for prevention of hepatitis B through vaccination reflect the varying epidemiology of HBV infection in different areas of the world.[96] In the United States, for example, infection is of comparatively low endemicity and occurs primarily in adolescents and adults. The risk for acquiring infection, however, is much greater in certain populations. Examples include those born and living in areas or among groups in which HBV is highly endemic and those with lifestyles predisposing to the acquisition of HBV, such as male homosexual activity, intravenous drug abuse, and promiscuous heterosexual activity.[6] In contrast, in geographic areas in which HBV infection is highly endemic, infection usually is acquired at birth or during childhood, a pattern resulting in the recommendation for universal vaccination of infants.

In 1991, the CDC initiated a comprehensive hepatitis B vaccination strategy to eliminate transmission of HBV in the United States.[96] Critical elements of this strategy included preventing perinatal transmission of HBV by identifying and providing immunoprophylaxis to infants of HBsAg-positive mothers and universal hepatitis B vaccination of infants to interrupt transmission and prevent future infection. The advantages of this approach included the existence of effective programs of routine childhood immunization, protection without any need to identify specific risk factors, and protection before significant exposure occurred. In addition, the positive effects of universal infant immunization had been observed in Taiwan, where the strategy of universal infant immunization already was being used. In Taiwan, the overall prevalence rate of HBV for children aged 1 to 10 years decreased from 9.8 percent in 1984 to 1.3 percent in 1994.[188]

In 1994, the ACIP expanded the recommendations to include previously unvaccinated children 11 to 12 years old.[172] In October 1997, these recommendations were expanded still further to include all unvaccinated children from birth to 18 years old and made hepatitis B vaccine available through the Vaccines for Children (VFC) program for persons from birth to 18 years of age who are eligible for this program.[178] The goal of the 1997 recommendations was to increase access to hepatitis B vaccine by encouraging the vaccination of previously unvaccinated children and adolescents from birth to 18 years old whenever they are seen for routine medical visits.[125] This expansion of the recommended age group for receiving vaccination and for VFC eligibility simplifies previous recommendations and the eligibility criteria for receiving VFC vaccine. The other ACIP priorities for giving hepatitis B vaccination to children remained unchanged and included the following groups: all infants; children in populations at high risk for acquiring HBV infection, such as Alaska Natives, Pacific Islanders, and children who reside in households of first-generation immigrants from countries where HBV infection is moderately or highly endemic; previously unvaccinated children 11 to 12 years old; and older adolescents and adults in defined at-risk groups.[96,172]

Between 1990 and 2004, the incidence of HBV infection in the United States declined by 75 percent. The decline was greatest among children and adolescents. Coincident with the decline in HBV incidence, vaccine coverage for children aged 19 to 35 months increased from 16 to 92 percent from 1991 to 2004.[135] Among adolescents 13 to 15 years old, according to CDC data, vaccine coverage increased from zero to 74 percent between 1993 and 2004. Clearly, since its inception in 1991, many aspects of the national immunization strategy to eliminate HBV transmission have been implemented with great success, especially the routine vaccination of all infants. Nonetheless, many challenges remain.

Despite the overall decline in hepatitis B incidence and the recommendations for routine vaccination of infants and children, increasing proportions of new HBV infections in the United States occur among adolescents and adults who have defined risk factors, including persons with multiple sex partners (more than one partner during

the preceding 6 months), men who have sex with men, and injecting drug users.[384] The primary means of preventing these infections is to identify settings such as correctional facilities, sexually transmitted disease clinics, and drug treatment centers where adolescents and adults with high-risk drug and sexual practices can be routinely accessed and vaccinated. In correctional facilities where previously unvaccinated inmates are offered HBV vaccination, 60 to 80 percent of inmates offered accepted vaccination.[566]

Even though universal screening of all pregnant women has been widely adopted across the United States, fewer than half of all HBsAg-positive pregnant women are identified through prenatal screening.[251] These women with unknown HBsAg status are not screened consistently, even when they are hospitalized during labor and delivery; consequently, their infants do not receive appropriate postexposure prophylaxis.[526] Furthermore, the birth dose of HBV vaccine, which could serve as a safety net for infants born to mothers for whom testing either was not performed or not performed correctly, was administered to only 45 percent of infants born in the United States in 2004, less than the rate of 54 percent seen before July of 1999, when recommendations were made to suspend the birth dose of hepatitis B vaccine temporarily until a thimerosal-free vaccine became available.[382]

To enhance existing strategies aimed at prevention of perinatal HBV transmission, the ACIP recommended in December of 2005 that all delivery hospitals institute specific policies and procedures to improve identification of infants born to HBsAg-positive mothers and mothers with unknown HBsAg status. These recommendations were made to ensure administration of appropriate postexposure prophylaxis and a birth dose of HBV vaccine to all medically stable infants. This statement also updated recommendations to improve vaccination coverage of adolescents and children by implementing immunization record reviews for all children 11 to 12 years old and children younger than 19 years of age who were born in countries with high or intermediate HBV endemicity and vaccinating all unvaccinated adolescents in settings that provide health care services to this age group.[399]

Preparations

Hepatitis B vaccines consisting of inactivated purified HBsAg derived from chronic hepatitis B plasma were introduced first in the early 1980s. In the late 1980s, two recombinant vaccines (Recombivax HB, Merck & Co.; and Engerix-B, SmithKline Beecham Biologicals) were licensed in the United States and currently are available in both single-antigen and combined formulations. Only the recombinant vaccines are available in the United States, but plasma-derived vaccines are widely used in other areas of the world. The recombinant vaccines contain 5 to 40 μg/mL of HBsAg protein. Pediatric formulations contain no thimerosal or only trace amounts. Vaccine is administered intramuscularly in the anterolateral thigh or deltoid area, depending on the age and size of the recipient. Administration in the buttocks or intradermally has been associated with decreased immunogenicity and is not recommended at any age.

Immunogenicity and Efficacy

The recommended series of three doses of vaccine induces a protective antibody response in more than 95 percent of infants, children, adolescents, and adults younger than 40 years.[16,399] In field trials, efficacy has been 80 to 95 percent and generally correlates with immunogenicity. Protection against disease is virtually 100 percent for persons who develop adequate serum antibody concentrations (anti-HBs ≥10 mIU/mL) after receiving vaccination. Adults older than 40 years of age and immunosuppressed persons are less likely to develop protective anti-HBs concentrations.

Hepatitis B vaccine is highly immunogenic. Therefore, postvaccination serologic testing is not indicated, with the exception of infants born to HBsAg-positive women, persons with ongoing occupational exposure to blood, and persons with immunosuppressive conditions. Active immunization in combination with passive immunoprophylaxis with hepatitis B immune globulin (HBIG) administered within 12 to 24 hours after birth to infants born to chronically infected mothers is more than 90 percent effective in preventing transmission of HBV to the infant. Active postexposure vaccination without HBIG administered soon after birth has been shown to be effective in preventing perinatal transmission and is used in areas where the use of HBIG is impractical.[282]

Vaccine-induced protection against symptomatic infection in a normal host is prolonged and correlates with immunologic memory, which has been demonstrated in immunized children and adults for at least 12 years after vaccination. Children immunized at birth are protected for at least 10 years. Thus, a need for routine booster doses has not been demonstrated.

Vaccine failures related to HBV variants with mutations in the S gene leading to conformational changes in the HBsAg protein, the major target for neutralizing anti-HBs antibody, have occurred in fully vaccinated children and perinatally exposed infants who received appropriate active and passive postexposure prophylaxis and in many cases had protective anti-HBs antibody levels.[315] Although no evidence to date establishes that these escape mutations pose a threat to the effectiveness of current hepatitis B vaccine programs, future surveillance to detect emergence of HBV variants in immunized populations is warranted.[399,595]

Adverse Events

Other than soreness at the injection site, reactions to hepatitis B vaccine rarely occur. Postvaccination surveillance performed after licensure of the plasma-derived vaccine indicated a possible association between Guillain-Barré syndrome and receipt of the first vaccine dose, but no evidence indicates an association of Guillain-Barré syndrome with recombinant vaccine.[399,400] Anaphylaxis has been estimated to occur in 1 in 600,000 doses distributed.[399,400] Several nonfatal cases have been reported in children.

Indications

Routine immunization with hepatitis B vaccine is recommended for all infants in the United States and should be completed by 6 to 18 months of age for all infants born to HBsAg-negative mothers.[15,399] Delivery hospitals should develop policies that ensure administration of a birth dose for all infants weighing 2000 g or more at birth unless a physician's order to defer immunization is in place and the serologic status of the mother is in the infant's medical record. Administering the first dose of hepatitis B vaccine soon after birth should minimize the risk for development of infection because of errors in maternal HBsAg testing or reporting or from exposure to persons with chronic HBV infection in the household and can increase the likelihood of completing the vaccine series. For infants weighing less than 2 kg who are born to HBsAg-negative mothers, initiation of vaccine should begin starting at 1 month of chronologic age. Administration of the second dose of vaccine is recommended 1 to 2 months after administration of the first dose, followed by a third dose when the infant is 6 to 18 months of age.

Only single-antigen hepatitis B vaccine can be used for doses given to infants between birth and 6 weeks of age. Single-antigen or combination vaccine may be used to complete the series; four doses of vaccine may be administered if a birth dose is given and a combination vaccine containing a hepatitis B component is used to complete the series.

Routine screening of all pregnant women for HBsAg is recommended because of the necessity for administering a birth dose of vaccine and HBIG.[16,399] Infants born to HBsAg-positive mothers, including pre-term and low-birth-weight infants, should be given HBIG (0.5 mL) within 12 hours of birth at a separate injection site, as well as the birth dose of HBV vaccine.[16,399] If a pre-term infant weighing less than 2000 g is born to an HBsAg-positive mother, the birth dose of hepatitis B vaccine should not be counted toward completion of the vaccine series and three additional doses of hepatitis B vaccine should be administered beginning when the child is 1 month of age. In addition to receiving HBIG and the hepatitis B vaccine series, infants of HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) at 9 to 15 months of age to identify those with chronic HBV infection or those who may require re-vaccination.[399]

A woman whose HBsAg status is unknown at delivery should undergo blood testing as soon as possible to determine her HBsAg status. The infant should receive the first dose of hepatitis B vaccine within 12 hours. If the woman is found to be HBsAg-positive, her infant should receive HBIG as soon as possible within 7 days. In populations where HBsAg testing of pregnant women is not feasible, all infants should receive hepatitis B vaccine at birth and 2 months and complete the series by the time they reach 6 months of age.

Hepatitis B vaccination is recommended for all children and adolescents younger than 19 years old in the United States. Children who have not been immunized previously may begin the vaccine series during any visit. All children aged 11 to 12 years old should have a review of their immunization records and receive the complete hepatitis B vaccine series if they have not been vaccinated previously. All children and adolescents younger than 19 years old who were born in Asia, the Pacific Islands, Africa, or other intermediate- or high-endemic countries or have at least one parent who was born in one of these areas should have a review of their immunization records and complete the hepatitis B vaccine series if they were not vaccinated previously.[399]

Vaccination also is recommended for those with one or more of the following risk factors for acquiring HBV infection[16]:

- Sexually active adolescents and adults who have a recently acquired sexually transmitted disease, are seeking evaluation or treatment for a sexually transmitted infection, are identified as prostitutes, or have had one or more sex partners in the previous 6 months
- Sexually active men who have sex with men
- Household contacts or sexual partners of HBsAg-positive persons
- Injecting drug users
- Persons at occupational risk for acquiring infection through exposure to blood or blood-contaminated body fluids, such as health care workers and public safety workers
- Residents and staff of institutions for the developmentally disabled
- Patients undergoing hemodialysis (vaccination of those with early renal failure is encouraged before they require hemodialysis)
- Patients with human immunodeficiency virus (HIV) infection, chronic liver disease, and diabetes mellitus
- Members of households with international adoptees who are HBsAg positive
- Travelers, especially children, to areas with high and intermediate rates of infection with HBV who have close contact with the local population or are likely to have contact with blood, such as in a medical setting, or sexual contact with residents
- Inmates in long-term correctional facilities

In addition to active and passive immunoprophylaxis of infants born to HBsAg-positive mothers, post-exposure prophylaxis is recommended in the following circumstances:

- Sexual partner of an HBsAg-positive person. A single dose of HBIG within 14 days of the last sexual contact and initiation of the three-dose hepatitis B vaccination is recommended for susceptible persons.
- Household exposure or close contact of an unvaccinated infant younger than 12 months old to a primary caregiver who has acute or chronic hepatitis B infection. Infants in this circumstance should receive HBIG, in addition to being vaccinated against hepatitis B. If, at the time of exposure only one dose of vaccine has been administered, the second dose should be administered if the interval is appropriate or HBIG should be administered if immunization is not yet due. If the infant has been immunized fully or has received at least two doses

of vaccine, the infant should be presumed protected and HBIG is not required.

- Accidental percutaneous or per mucosal exposure of a susceptible person to HBsAg-positive blood. This indication is exemplified most by a needle stick or other accident involving blood in a hospital. Another example is an injury to a susceptible person caused by the bite of an HBsAg-positive child. For this indication, HBIG as well as vaccine is given. Recommendations in these circumstances are complex and based on the availability of the blood source for HBsAg testing and the hepatitis B vaccination status of the exposed person.

Booster doses are not recommended except in the case of patients undergoing hemodialysis and possibly other immunocompromised patients, in whom annual antibody testing should assess the need. An additional dose is indicated for those whose serum anti-HBsAg concentration is less than 10 mIU/mL.

The current recommended doses and schedule for the use of hepatitis B vaccines licensed in the United States in infants and other age groups are shown in Table 244-11 (see elsewhere for more information[15,399,400]). For completing the hepatitis B vaccine series and achieving complete vaccination for hepatitis B, the two licensed hepatitis B vaccines are interchangeable when administered in doses recommended by the manufacturers.[16,399] In September of 1999, the FDA approved an optional two-dose schedule of Recombivax HB for vaccination of adolescents 11 to 15 years of age. The ACIP recommended that this schedule be included in the VFC program in February 2000.[136] With the two-dose schedule, the adult dose of Recombivax HB is administered to adolescents 11 to 15 years old, with the second dose given 4 to 6 months after the first dose. In immunogenicity studies in adolescents 11 to 15 years of age, antibody concentrations and seroprotection rates were similar with the two-dose schedule and the currently licensed three-dose schedule. Follow-up data collected during the course of 2 years indicate that the rate of decline in concentration of antibody for the two-dose schedule was similar to that for the three-dose schedule. No data are available to assess long-term protection or immune memory after vaccination with the two-dose schedule, and whether booster doses of vaccine will be required is not known. Children and adolescents who have begun vaccination with a dose of the pediatric formulation should complete the three-dose series with this dose. Similarly, if the formulation administered to an adolescent at the start of a series is not known, the series should be completed with the three-dose schedule.

A combination of hepatitis B (Engerix-B, 20 μg) and hepatitis A (Havrix, 720 enzyme-linked immunosorbent assay units [ELU]) vaccine (called Twinrix) is licensed for use in persons 18 years of age and older in a three-dose schedule administered at birth, 1 month, and 6 or more months later. Alternately, a four-dose schedule at birth and days 7 and then 21 to 30 followed by a booster dose at 12 months was approved in 2007 and may be used.[16]

In December of 2006, the ACIP approved recommendations for hepatitis vaccine use in adults.[400] In settings in which high proportions of adults have risks for acquiring HBV infection, the ACIP recommends universal hepatitis B vaccination for all unvaccinated adults. These settings include (1) sexually transmitted infection treatment facilities; (2) HIV testing and treatment facilities; (3) facilities providing drug abuse treatment and prevention services; (4) health care settings targeting services to injection drug users; (5) correctional facilities; (6) health care settings serving men who have sex with men; (7) chronic hemodialysis facilities and end-stage renal disease programs; and (8) institutions and nonresidential care facilities for persons with developmental disabilities. In other primary care and specialty medical settings in

TABLE 244-11 **Recommended Doses and Schedules of Hepatitis B Virus Vaccines in the United States**

Group	Recombivax HB Dose μg (mL)	Engerix-B Dose μg (mL)
Infants of HBsAg-negative mothers, children, and adolescents <20 yr	5 (0.5)	10 (0.5)

Data from references 16, 399, and 400.

which adults at risk for developing HBV infection receive care, the ACIP recommends that health care providers should inform all patients about the health benefits of vaccination, including risks for acquiring HBV infection, and persons for whom vaccination is recommended and should vaccinate adults who report having risks for developing HBV infection and any adults requesting protection from HBV infection. To promote vaccination in all settings, health care providers should implement standing orders to identify adults recommended for hepatitis B vaccination and administer vaccination as part of routine clinical services, not require acknowledgment of an HBV infection risk factor for adults to receive vaccine, and use available reimbursement mechanisms to remove financial barriers to receiving hepatitis B vaccination. In 2011, the ACIP recommended that all previously unvaccinated adults aged 19 through 59 years with diabetes mellitus (type 1 and type 2) be vaccinated against hepatitis B as soon as possible after a diagnosis of diabetes is made. Unimmunized adults with diabetes mellitus who are 60 years of age or older may be vaccinated at the discretion of the treating clinician after assessing their risk.[186]

Contraindications

The only contraindication to receiving HBV vaccination is a history of anaphylaxis to a previous dose of vaccine. Although data on the safety of HBV vaccines are not available for pregnant women, these vaccines contain only HBsAg and not live virus and should not be deleterious to the developing fetus. Because HBV infection during pregnancy can result in transmission to the neonate, susceptible women at increased risk for acquiring infection should be vaccinated during pregnancy. Inadvertent vaccination of HBsAg-positive persons has no deleterious effects.

Human Papillomavirus Vaccine

Genital HPV infection is thought to be the most common sexually transmitted viral infection, accounting for 6.2 million new cases annually in the United States.[94] The estimated prevalence of HPV infection ranges from 20 to 40 percent among sexually active 20-year-old women.[381] HPV typically infects girls and women soon after sexual exposure.[207,573] Median time from first intercourse to first detection of HPV is only 3 months.[207] The lifetime risk for women to acquire one or more genital HPV infections exceeds 75 percent.[94,381]

More than 40 HPV types can infect the genital tract and are classified on the basis of their association with cervical cancer.[429] The "low-risk," nononcogenic HPV types (e.g., types 6 and 11) are associated with anogenital warts, mild cervical dysplasia, and recurrent respiratory papillomatosis. The "high-risk" oncogenic HPV types are causally linked to several human cancers in both women and men, including cancers of the cervix, vulva, vagina, anus, and penis and a subset of head and neck cancers.[381] Infection with HPV causes virtually all cases of cervical cancer, the second most common cause of death from cancer among women globally, surpassed only by breast cancer.[381] The development of cervical cancer often occurs decades after initial infection. HPV types 16 and 18 account for 70 percent of cervical cancers.[199] A variety of other types account for the remaining 30 percent of cervical cancers, and these types vary in their distribution globally.

Although the incidence of HPV is high, most infections clear without intervention. Seventy percent of new infections clear within 1 year, and 91 percent clear within 2 years.[199] Persistent infection with high-risk HPV types, defined as detection of the same viral type at two or more visits 6 months apart, is the most important risk factor for development of cervical cancer precursor lesions. Studies have demonstrated that persistent infection with a high-risk HPV type is associated with a greater than 10-fold risk for high-grade cervical cancer precursors.[312,420]

A first generation of prophylactic HPV subunit vaccines has been developed.[355] These vaccines are expected to have a significant impact on the incidence of HPV-related cervical and other anogenital cancers in women. Incidence of recurrent respiratory papillomatosis also is likely to decrease as a result of widespread vaccination.

Preparations

In 2006, the FDA licensed the first HPV vaccine for use in girls and women 9 through 26 years of age in the United States, and this was done for use in males 9 through 26 years of age in 2009.[17,157,394] This quadrivalent vaccine (GARDASIL, Merck & Co.) contains HPV types 6, 11, 16, and 18 virus-like particles (VLPs) and protects against four HPV types, which together cause 70 percent of cervical cancers (HPV types 18 and 16) and 90 percent of genital warts (HPV types 6 and 11).

The quadrivalent HPV vaccine (HPV4) is prepared from the highly purified VLPs of the major capsid (L1) protein of HPV types 6, 11, 16, and 18. The L1 proteins are produced by *Saccharomyces cerevisiae* and self-assemble into VLPs. The VLPs mimic the HPV virus, but they contain no viral DNA. Each 0.5-mL dose contains 20 µg HPV 6 L1 protein, 40 µg HPV 11 L1 protein, 40 µg HPV 16 L1 protein, and 20 µg HPV 18 L1 protein.

A bivalent vaccine (CERVARIX, GlaxoSmithKline) which is directed against two oncogenic HPV types (16 and 18) was licensed for use in females 10 through 25 years of age in 2009 and not licensed for males.[17,118] The quadrivalent and bivalent HPV vaccines use alum as an adjuvant and do not contain thimerosal or antibiotics. The vaccines should be stored at 2°C to 8°C (36°F to 46°F) and not frozen.[118]

Primary vaccination dosing schedules with the quadrivalent and bivalent HPV vaccine are the same and consist of three 0.5-mL doses administered intramuscularly. The second and third doses should be administered 2 and 6 months after administration of the first dose.

Immunogenicity and Efficacy

Early data from randomized controlled trials have shown consistently that prophylactic HPV VLP vaccines are immunogenic and efficacious in preventing infection and

lesions caused by the targeted HPV types.[301,355,381,411,514] Vaccine efficacy seems to be mediated by a type-specific humoral immune response. Evaluations of the quadrivalent HPV4 vaccine have demonstrated that vaccinated individuals develop high antibody titers to the respective HPV types that exceed the antibody titers seen with natural HPV infection.[514] However, the level of antibody that confers a protective response is unknown.[514] For the quadrivalent HPV VLP vaccine, an antibody response significantly greater than placebo was sustained for at least 3 years without booster doses.[301,551] Although vaccine efficacy studies have been done only in adolescents ages 13 years and older, immunogenicity bridging studies have been performed in children as young as 9 years of age. Antibody titers to HPV types 6, 11, 16, and 18 were found to be higher in younger adolescents than in young adults. From these data, investigators inferred that protection exists against cervical cancer, cancer precursor lesions, and genital warts, even for young adolescent girls who receive the quadrivalent vaccine.

The results from four randomized controlled trials repeatedly demonstrate that a regimen of three intramuscular injections of HPV VLP vaccine provides high-level protection from infection and lesions caused by targeted HPV types.[355,381] Efficacy from a combined analysis of quadrivalent HPV vaccine efficacy from both phase II and phase III clinical trials is 100 percent against precancerous lesions (carcinoma in situ II/III or adenoma in situ) caused by HPV type 16 or 18 and is 99 percent against development of genital warts.[411] It is not known whether HPV vaccines provide long-term protection and whether booster doses will be necessary. The quadrivalent HPV4 vaccine has not been found to have efficacy against existing disease or infection caused by HPV.

Bivalent vaccine (HPV2) efficacy was evaluated in two randomized, double-blind, controlled clinical trials in females aged 15 through 25 years. In the analysis, 99 percent or more of participants developed an HPV 16 and 18 antibody response 1 month after completing the three-dose series. In addition, after concomitant administration of HPV2 with tetanus toxoid, diphtheria toxoid, and acellular pertussis vaccine and/or with meningococcal conjugate vaccine in females aged 11 through 18 years compared with those after administration at separate visits, the antibody responses for bivalent vaccine antigens were noninferior.[118]

HPV4 and HPV2 vaccines are highly effective in preventing HPV 16- and 18-related cervical precancerous lesions in females. The quadrivalent vaccine is highly effective in preventing HPV 6- and 11-related genital warts in females and males, and HPV4 vaccine also has been shown to be effective in preventing anal precancerous lesions in males. Vaccines offer no protection against progression of infection to disease from HPV acquired before immunization.[17]

Adverse Events

HPV vaccines appear to be generally safe and well tolerated. The quadrivalent HPV vaccine has been associated with minimal adverse reactions.[240] The most common are mild fever (<38°C [100.4°F]) and local injection site reactions such as pain, redness, pruritus, or swelling. Additional data on vaccine safety, including data on pregnancy and fetal and infant outcomes, are being collected in ongoing trials and will continue to be collected in post-licensure studies.

In analyses of local and general adverse events after bivalent HPV2 vaccine administration versus control vaccines, 92 percent reported injection-site pain; 48 percent, redness; and 44 percent, swelling in the HPV2 group. These findings compared with 64 to 87 percent, 24 to 28 percent, and 17 to 21 percent in the control groups for the same findings. Fatigue, headache, and myalgia were the most common general symptoms noted.[118]

Indications

The ACIP issued recommendations for the use of the quadrivalent HPV vaccine in March 2007 and for the bivalent HPV2 vaccine in May 2010.[118,119,157,394] Routine vaccination with three doses of either vaccine is recommended for girls 11 to 12 years of age. The vaccination series can be started in girls as young as 9 years of age, with physician and parental discretion. Catch-up vaccination is recommended for girls and women 13 to 26 years old who have not been vaccinated previously or who have not completed the full vaccination series. Only HPV4 vaccine is recommended for routine immunization of males at 11 or 12 years of age (the series can be started at 9 years of age) and also is recommended for males 13 through 21 years of age not previously immunized. Males 22 through 26 years of age may be immunized upon request. Vaccine is recommended for men who have sex with men and males who are immunocompromised (including those with HIV infection) through 26 years of age. Ideally, vaccination should be administered before potential exposure to HPV through sexual contact occurs. Neither quadrivalent or bivalent vaccines are licensed for use in persons older than 26 years of age.[17]

Vaccine is administered in a three-dose schedule, and the second and third doses should be administered 2 and 6 months after the first dose. Immunogenicity data allow for some degree of flexibility in the dosing schedule, which is often an important consideration in providing multidose vaccines to adolescents for whom contact with health providers can be sporadic. For both vaccines, the minimum interval from dose 1 to dose 2 is 4 weeks. The minimum interval from dose 2 to dose 3 should not be less than 12 weeks.

HPV vaccine can be administered at the same visit when other age-appropriate vaccines, such as Tdap, Td, and MCV4 (meningococcal), are provided. Women who have received an HPV vaccine must continue to have regular Papanicolaou test screening. HPV vaccines do not provide protection against all HPV types associated with development of cancer, and vaccines do not alter the progression of HPV infection acquired before immunization.

Persons through 26 years of age with evidence of current HPV infection, such as cervical dysplasia, a positive HPV DNA test result, or anogenital warts or a history of anogenital warts, should receive HPV

immunization because infection with all vaccine HPV types is unlikely and the vaccine could provide protection against HPV infection with types not already acquired.[17] Vaccine recipients should be advised that data from clinical trials do not indicate the vaccine will have any therapeutic effect on existing abnormalities found by Papanicolaou testing, on HPV infection, or on genital warts. However, HPV vaccination would provide protection against infection with vaccine HPV types not already acquired.

Lactating women can receive quadrivalent HPV vaccine, but the bivalent vaccine has not been studied in lactating women. Patients of the appropriate age who are immunocompromised from either disease or medication can receive HPV vaccine. However, the immune response to vaccination and vaccine effectiveness may be less than in those who are immunocompetent. HPV vaccine falls into pregnancy category B and is not recommended for use in pregnancy.[118] If an adolescent becomes pregnant during vaccination, subsequent doses should be deferred until after parturition. The vaccine has not been associated causally with adverse outcomes of pregnancy or adverse events to the developing fetus. However, data on vaccination during pregnancy are limited at this time.

Contraindications

Quadrivalent HPV4 vaccine is contraindicated for persons with a history of immediate hypersensitivity to yeast or to any vaccine component. Bivalent HPV2 vaccine is contraindicated for persons with a history of immediate hypersensitivity to any vaccine component. HPV2 vaccine in the prefilled syringe formulation should not be administered to latex-sensitive individuals, because the rubber stopper contains latex.[17]

Influenza Vaccine

Influenza virus infection continues to cause significant morbidity and mortality despite the availability of effective vaccines and antiviral therapy for prevention and treatment of influenza. In the United States, epidemics of influenza typically occur during the winter months and have been associated with an average of approximately 36,000 deaths per year in the United States.[529]

Influenza viruses cause disease among all age groups.[274,275,424] Rates of infection are highest among children, but rates of serious illness and death are highest among persons aged 65 years and older, children aged 2 years and younger, and persons of any age who have medical conditions that place them at increased risk for developing complications from influenza.[64,65,273,424] The impact of influenza on both normal children and those with underlying high-risk conditions is appreciable. Attack rates in normal children have been estimated at 10 to 40 percent each year, and approximately 1 percent of these influenza infections result in hospitalization.[276,467]

A major difficulty in the development and provision of satisfactory immunizing agents for the prevention of influenza is the antigenic variation in these viruses. Periodic minor antigenic changes in influenza A or B virus are the major factors in the continuing occurrence of yearly influenza. Although outbreaks generally are limited in magnitude, the resulting morbidity and mortality remain discouragingly high. Major antigenic changes in influenza A virus, as occurred in 1957 to 1958 (Asian strain), in 1968 to 1969 (Hong Kong strain), and again in 2009 (pH1N1) account for the pandemic spread of disease associated with greater overall morbidity and mortality. The CDC estimates that in the 2009 pandemic the H1N1 influenza virus caused more than 60 million Americans to become ill and led to more than 270,000 hospitalizations and 12,500 deaths.[332] Ninety percent of hospitalizations and deaths occurred in persons younger than 65 years of age. With typical seasonal influenza, approximately 90 percent of deaths occur in persons older than 65 years.

Preparations

Two types of influenza vaccines are licensed for use in the United States: inactivated trivalent influenza vaccine (TIV) and live attenuated influenza vaccine (LAIV).[19,44,144] These multivalent vaccines contain three virus strains (usually two type A and one type B), with the composition changed periodically in anticipation of the prevalent influenza strains expected to circulate in the United States in the following winter. Both vaccines are prepared from virus grown in the allantoic sac of the chick embryo. All vaccines contain the same antigenic composition, and there is no preferential recommendation for any of the formulations of TIV or LAIV.

TIV is an inactivated vaccine that contains no live virus. TIV distributed in the United States consists of either subvirion vaccine, prepared by disrupting the lipid-containing membrane of the virus, or purified surface-antigen vaccine. TIV formulations are now available for intramuscular (IM) and intradermal (ID) use.

The IM formulation of TIV is licensed and recommended for children aged 6 months or older and adults, including persons with and without chronic medical conditions. Vaccine is available in both pediatric (0.25-mL dose) and adult (0.5-mL dose) formulations. TIV is administered intramuscularly into the anterolateral thigh of infants and young children and into the deltoid muscle of older children and adults. The volume of vaccine is age dependent; infants and toddlers 6 months through 35 months of age should receive a dose of 0.25 mL, and all individuals 3 years (36 months) and older should receive 0.5 mL per dose. Children younger than 9 years of age who are being immunized against influenza for the first time should receive two doses of TIV given 4 weeks apart, before the start of the influenza season. The IM formulation of TIV is shipped and stored at 2° C to 8° C (35° F to 46° F).

The ID formulation of TIV is licensed for the 2012-2013 influenza season for use in individuals aged 18 through 64 years. It is administered intradermally preferably over the deltoid muscle and only by using the device included in the vaccine package. Vaccine is supplied in a single-dose, prefilled microinjection system (0.1 mL). The ID formulation of TIV is shipped and stored at 2° C to 8° C (35° F to 46° F).

Multiple manufacturers produce inactivated influenza vaccine each year for the U.S. market. Vaccines are available in multiple presentations (single-dose syringes and vials, multidose vials) and in preservative-free formulations. Approved age indications vary by manufacturer and product. Clinicians should obtain inactivated influenza vaccine appropriate for the age groups they plan to vaccinate. The ACIP does not recommend use of influenza vaccine outside the vaccine's FDA-approved age indication. Tables listing each year's influenza vaccines are available in the annual ACIP and American Academy of Pediatrics influenza statements and on the CDC influenza website.* Package inserts should be consulted for recommended age groups and possible contraindications for each vaccine in addition to information regarding additional components of various vaccine formulations.

LAIV is cold adapted, developed by passaging the viruses at successively lower temperatures in tissue culture, so that replication occurs only in the upper respiratory tract.[73] LAIV is administered intranasally. The cold-adapted formulation that is licensed in the United States must be stored at 2° to 8° C (35° F to 46° F). When the vaccine is warmed to room temperature for intended use, it must be used within 30 minutes.

LAIV is licensed by the FDA for healthy individuals aged 2 through 49 years. It is not recommended for those who have a history of asthma or other high-risk medical conditions associated with an increased risk for complications from influenza. LAIV is administered intranasally in a prefilled, single-use sprayer containing 0.2 mL of vaccine. A removable dose-divider clip is attached to the sprayer to administer 0.1 mL separately into each nostril. Children younger than 9 years of age being immunized against influenza for the first time should receive two doses of LAIV given 4 weeks apart, before the start of the influenza season. LAIV formulation currently licensed in the United States must be shipped and stored at 2° C to 8° C (35° F to 46° F)

All currently available influenza vaccines are trivalent and contain A(H1N1), A(H3N2), and B viral antigens. There are two antigenically distinct lineages of influenza B viruses referred to as Victoria and Yamagata lineages.[406] Immunization against B virus strains of one lineage provides limited cross protection against strains in the other lineage.[72] Because of this and the difficulty of predicting which B virus lineage will predominate during a given season, inclusion of a second influenza B vaccine virus strain in seasonal influenza vaccines has been proposed. In February 2012, FDA approved a new seasonal quadrivalent LAIV, FluMist Quadrivalent (MedImmune). This vaccine currently is anticipated to be available for the 2013-14 influenza season, at which time it is expected to replace the currently available seasonal trivalent FluMist formulation. Inactivated quadrivalent influenza vaccines currently are in development.

Immunogenicity and Efficacy

Children aged 6 months and older typically have protective levels of anti-influenza antibody against specific influenza virus strains after receiving the recommended number of doses of seasonal inactivated influenza vaccine.* Immunogenicity studies using the influenza A (H1N1) 2009 monovalent vaccine indicated that more than 90 percent of children aged 9 years or older responded to a single dose with anti-influenza antibody levels that are considered to be protective. Young children had inconsistent responses to a single dose of the influenza A (H1N1) 2009 monovalent vaccine across studies, with 20 percent of children aged 6 to 35 months responding to a single dose with protective anti-influenza antibody levels. However, in all studies, 80 to 95 percent of vaccinated infants, children, and adolescents developed protective anti-influenza antibody levels to the 2009 H1N1 influenza virus after two doses.[55,439,464]

In most seasons, one or more seasonal vaccine antigens are changed compared with the previous season. In consecutive years when vaccine antigens change, children aged younger than 9 years who received only one dose of vaccine in their first year of vaccination are less likely to have protective antibody responses when administered only a single dose during their second year of vaccination compared with children who received two doses in their first year of vaccination.[248,435,556]

When the vaccine antigens do not change from one season to the next, priming children aged 6 to 23 months with a single dose of vaccine in the spring followed by a dose in the fall results in similar antibody responses compared with a regimen of two doses in the fall.[247] However, one study conducted during a season when the vaccine antigens did not change compared with the previous season estimated 62 percent effectiveness against influenza-like illness (ILI) for healthy children who had received only one dose in the previous influenza season and only one dose in the study season compared with 82 percent for those who received two doses separated by 4 weeks or more during the study season.[5]

The antibody response among children at higher risk for influenza-related complications (e.g., children with chronic medical conditions) might be lower than those reported typically among healthy children.[70,285] However, antibody responses among children with asthma are similar to those of healthy children and are not substantially altered during asthma exacerbations requiring short-term prednisone treatment.[450]

Vaccine effectiveness studies also have indicated that two doses are needed to provide adequate protection during the first season that young children are vaccinated. Among children aged younger than 5 years who have never received influenza vaccine previously or who received only one dose of influenza vaccine in their first year of vaccination, vaccine effectiveness is lower compared with children who received two doses in their first year of being vaccinated. Two large retrospective studies of young children who had received only one dose of TIV in their first year of being vaccinated determined that no decrease was observed in ILI-related office visits compared with unvaccinated children.[5,474] Similar results were reported in a case-control study of children aged 6 to 59 months in which laboratory-confirmed influenza was the

*Centers for Disease Control and Prevention: http://www.cdc.gov/flu/.

*References 224, 279, 367, 433, 585, 586.

outcome measured.[505] These results, along with the immunogenicity data indicating that antibody responses are substantially higher when young children are given two doses, are the basis for the recommendation that all children aged 6 months to 8 years who are being vaccinated for the first time should receive two vaccine doses separated by 4 weeks or more.

Estimates of vaccine efficacy or effectiveness among children aged 6 months or older have varied by season and study design. In a randomized trial conducted during five influenza seasons (1985-1990) in the United States among children aged 1 to 15 years, annual vaccination reduced laboratory-confirmed influenza A substantially (77% to 91%).[434] A limited 1-year placebo-controlled study reported vaccine efficacy against laboratory-confirmed influenza illness of 56 percent among healthy children aged 3 to 9 years and 100 percent among healthy children and adolescents aged 10 to 18 years.[200] A randomized, double-blind, placebo-controlled trial conducted during two influenza seasons among children aged 6 to 24 months indicated that efficacy was 66 percent against culture-confirmed influenza illness during the 1999-2000 influenza season but did not reduce culture-confirmed influenza illness substantially during the 2000-2001 influenza season.[313] A case-control study conducted during the 2003-2004 season indicated vaccine effectiveness of 49 percent against laboratory-confirmed influenza.[505] An observational study among children aged 6 to 59 months with laboratory-confirmed influenza compared with children who tested negative for influenza reported vaccine effectiveness of 44 percent in the 2003-2004 influenza season and 57 percent during the 2004-2005 season.[245] Partial vaccination (only one dose for children being vaccinated for the first time) was not effective in either study. During an influenza season (2003-2004) with a suboptimal vaccine match, a retrospective cohort study conducted among approximately 30,000 children aged 6 months to 8 years indicated vaccine effectiveness of 51 percent against medically attended, clinically diagnosed pneumonia or influenza (i.e., no laboratory confirmation of influenza) among fully vaccinated children and 49 percent among approximately 5,000 children aged 6 to 23 months.[474] Another retrospective cohort study of similar size conducted during the same influenza season in Denver but limited to healthy children aged 6 to 21 months estimated clinical effectiveness of 2 TIV doses to be 87 percent against pneumonia or influenza-related office visits.[5]

Among children, TIV effectiveness might increase with age.[434,589] A systematic review of published studies estimated vaccine effectiveness at 59 percent for children aged 2 years or older but concluded that additional evidence was needed to demonstrate effectiveness among children aged 6 months to 2 years.[331]

Because of the recognized influenza-related disease burden among children with other chronic diseases or immunosuppression and the long-standing recommendation for vaccination of these children, randomized placebo-controlled studies to study efficacy in high-risk children are needed but are currently unavailable. In a nonrandomized controlled trial among children aged 2 to 6 years and 7 to 14 years who had asthma, vaccine efficacy was 54 percent and 78 percent against laboratory-confirmed influenza type A infection and 22 percent and 60 percent against laboratory-confirmed influenza type B infection, respectively. Vaccinated children aged 2 to 6 years with asthma did not have substantially fewer type B influenza virus infections compared with the control group in this study.[519] The association between vaccination and prevention of asthma exacerbations is unclear. Vaccination was demonstrated to provide protection against asthma exacerbations in some studies.[356,442]

TIV has been demonstrated to reduce AOM in some studies. Two studies have reported that TIV decreases the risk for influenza-related otitis media by approximately 30 percent among children with mean ages of 20 and 27 months, respectively.[197,304] However, a large study conducted among children with a mean age of 14 months indicated that TIV was not effective against AOM.[313] Influenza vaccine effectiveness against a nonspecific clinical outcome such as AOM, which is caused by a variety of pathogens and is not typically diagnosed using influenza virus culture, is expected to be relatively low.

Adverse Events

TIV is an inactivated vaccine that contains killed viruses and therefore cannot produce signs or symptoms of influenza caused by active virus infection. The most common symptoms associated with TIV administration are soreness at the injection site and fever. Fever, usually occurring 6 to 24 hours after immunization, affects 10 to 35 percent of children younger than 2 years old. Mild systemic symptoms, such as nausea, lethargy, headache, muscle aches, and chills, also can occur after receipt of TIV.

An increased risk for febrile seizures after TIV administration had not been observed in the United States prior to the 2010-2011 influenza season.[284,296] During the 2010-2011 influenza season, the CDC and the FDA conducted enhanced monitoring for febrile seizures after influenza vaccination because of reports of an increased risk for fever and febrile seizures in young children in Australia associated with a 2010 Southern Hemisphere vaccine produced by CSL Biotherapies (up to nine febrile seizures per 1000 doses). Because of the findings in Australia, ACIP does not recommend the U.S.-licensed CSL Biotherapies' TIV, Afluria, for children aged younger than 9 years.[177]

Surveillance for U.S.-licensed influenza vaccines during the 2010-2011 season subsequently detected safety signals for febrile seizures in young children after TIV administration.[372,533] Further assessment determined that the increased risk was in children aged 6 months through 4 years on the day of vaccination to the day after (the 0- to 1-day risk window). The risk was higher when children received concomitant PCV13 and peaked at approximately age 16 months.[533] No increased risk was observed in children aged 5 years or older after TIV or in children of any age after LAIV. The magnitude of the increased risk for febrile seizures in young children in the United States (<1/1000 children vaccinated) was substantially lower than the risk observed in Australia in 2010.

After evaluating the data on febrile seizures from the 2010-2011 influenza season and taking into consideration benefits and risks of vaccination, no policy change was recommended for use of TIV or PCV13 for the 2011-2012 season. According to the CDC, surveillance data on febrile seizures in young children after administration of influenza vaccine for the 2011-2012 influenza season (same vaccine formulation as 2010-2011) were consistent with those from the 2010-2011 influenza season. No changes in the use of TIV or PCV13 are recommended for the 2012-2013 influenza season.

LAIV generally is well tolerated and may produce mild signs or symptoms related to influenza virus infection that include headache and runny nose or nasal congestion in vaccinees. Transmission of LAIV strains to unimmunized contacts has been documented only once in pre-licensure studies. The proposed explanation for the uncommon occurrence of transmission is that the vaccine virus is shed for a shorter duration and in a much smaller quantity than are wild-type strains.

Indications

Routine annual influenza vaccination is recommended for all persons aged 6 months or older. To permit time for production of protective antibody levels,[87,286] vaccination optimally should occur before onset of influenza activity in the community. Therefore, vaccination providers should offer vaccination as soon as vaccine is available. Vaccination should be offered throughout the influenza season (i.e., as long as influenza viruses are circulating in the community).[44,144]

Healthy children aged 2 years or older can receive either TIV or LAIV. Particular focus should be on the administration of TIV for all children and adolescents who have underlying medical conditions associated with an increased risk for complications from influenza, including the following:

- Asthma or other chronic pulmonary diseases, including cystic fibrosis
- Hemodynamically significant cardiac disease
- Immunosuppressive disorders or therapy
- HIV infection
- Sickle cell anemia and other hemoglobinopathies
- Diseases that require long-term aspirin therapy, including juvenile idiopathic arthritis or Kawasaki disease
- Chronic renal dysfunction
- Chronic metabolic disease, including diabetes mellitus
- Any condition that can compromise respiratory function or handling of secretions or can increase the risk for aspiration, such as neurodevelopmental disorders, spinal cord injuries, seizure disorders, or neuromuscular abnormalities

Although universal immunization for all individuals aged 6 months or older is recommended, particular immunization efforts, with either TIV or LAIV, should be made for the following groups to prevent transmission of influenza to those at risk, unless contraindicated:

- Household contacts and out-of-home care providers of children younger than age 5 years and at-risk children of all ages (healthy contacts 2 to 49 years of age can receive either TIV or LAIV).
- Any female who is pregnant, is considering pregnancy, has just delivered, or is breastfeeding during the influenza season (TIV only). Studies have shown that infants born to immunized women have better influenza-related health outcomes. However, the estimated median seasonal vaccination coverage among women with a live birth was only 47 percent during the 2009-2010 influenza season, even though both pregnant women and their infants are at higher risk for complications. In addition, data from some studies suggest that influenza vaccination in pregnancy may decrease the risk for preterm birth.
- Health care personnel or health care volunteers. Despite the recent AAP recommendation for mandatory influenza immunization for all health care personnel,[75] many remain unvaccinated. As of November 2011, the CDC estimated that only 63 percent of health care personnel received the seasonal influenza vaccine. The AAP recommends mandatory vaccination of health care personnel because they frequently come into contact in their clinical settings with patients at high risk for influenza illness.
- Close contacts of immunosuppressed persons

Previously unimmunized children between 6 months to 9 years of age should receive two doses of influenza vaccine before the onset of influenza season. Available data suggest that children younger than 9 years who did not receive the second dose of influenza vaccine in the initial year that influenza vaccine was given may not be adequately protected the next influenza season with only one dose. In this group, levels of protection can be suboptimal, especially if the antigenic specificity of the predominant strains has changed from the previous year. Thus, the AAP recommends that two doses be given to these children the following influenza season.[44] This recommendation applies only to the influenza season that follows the first year that a child younger than 9 years old receives influenza vaccine (Fig. 244-4).

Precautions and Contraindications

TIV is contraindicated in infants younger than 6 months and children who have a moderate to severe febrile illness, on the basis of clinical judgment of the pediatrician. Persons with acute febrile illness usually should not be vaccinated until their symptoms have abated. However, minor illnesses with or without fever do not contraindicate the use of influenza vaccine, particularly in children with mild upper respiratory tract infection or allergic rhinitis.[44,144]

Pregnancy is not a contraindication to influenza vaccine administration, and vaccination with TIV is advised for pregnant girls and women who have an underlying high-risk condition. LAIV is contraindicated in any female who is pregnant or considering pregnancy.

Children should not be vaccinated with LAIV if they are younger than 2 years, have a moderate to severe febrile illness, are receiving aspirin or other salicylates,

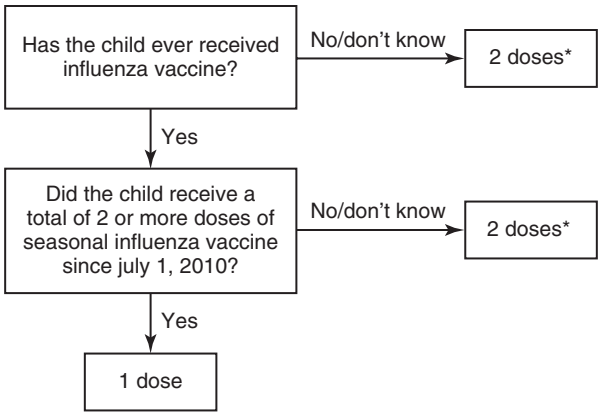

FIGURE 244-4 ■ Influenza vaccine dosing algorithm for children aged 6 months through 8 years—Advisory Committee on Immunization Practices, United States, 2012-2013 influenza season.
*Doses should be administered at least 4 weeks apart.
†For simplicity, this algorithm takes into consideration only doses of seasonal influenza vaccine received since July 1, 2010. As an alternative approach in settings where vaccination history from before July 1, 2010, is available, if a child aged 6 months through 8 years is known to have received at least two seasonal influenza vaccines during any previous season, and at least one dose of a 2009(H1N1)-containing vaccine (i.e., either 2010-2011 or 2011-2012 seasonal vaccine or the monovalent 2009[H1N1] vaccine), then the child needs only one dose for 2012-2013. Using this approach, children aged 6 months through 8 years need only one dose of vaccine in 2012-2013 if they have received any of the following: (1) two or more doses of seasonal influenza vaccine since July 1, 2010; (2) two or more doses of seasonal influenza vaccine before July 1, 2010, and one or more doses of monovalent 2009 (H1N1) vaccine; or (3) one or more doses of seasonal influenza vaccine before July 1, 2010, and one or more doses of seasonal influenza vaccine since July 1, 2010. Children for whom one of these conditions is not met require two doses in 2012-2013. (From Centers for Disease Control and Prevention. *Immunization schedules.* Available at http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6132a3.htm.)

have known or suspected immune deficiency disease, are receiving immunosuppressive or immunomodulatory therapies, or have a chronic underlying medical condition, including metabolic disease, diabetes mellitus, asthma, other chronic disorders of the pulmonary or cardiovascular system, renal dysfunction, or hemoglobinopathies. Children should not be given LAIV if they have received other live virus vaccines within the past 4 weeks; however, other live virus vaccines can be given on the same day as LAIV. Children with any condition that can compromise respiratory function or handling of secretions or can increase the risk for aspiration, such as neurodevelopmental disorders, spinal cord injuries, seizure disorders, or neuromuscular abnormalities should not receive LAIV.

Children aged 2 through 4 years with a history of recurrent wheezing or a medically attended wheezing episode in the previous 12 months should not receive LAIV because of the potential for increased wheezing after immunization. In this age range, many children have a history of wheezing with respiratory tract illnesses and are eventually diagnosed with asthma. Therefore, when offering LAIV to children 24 through 59 months of age, the health care provider should screen them by asking the parent/guardian the question, "In the previous 12 months, has a health care professional ever told you that your child had wheezing?" If a parent answers "yes" to this question, LAIV is not recommended for the child. TIV would be recommended for the child to whom LAIV is not given.

Children taking an influenza antiviral medication should not receive LAIV until 48 hours after stopping the influenza antiviral therapy. If a child recently received LAIV but has an influenza illness for which antiviral agents are appropriate, the antiviral agents should be given. Reimmunization may be indicated because of the potential effects of antiviral medications on LAIV replication and immunogenicity.

Precaution also should be taken when considering LAIV administration to persons with minor acute illness, such as a mild upper respiratory tract infection with or without fever. Although the vaccine most likely can be given in this case, LAIV should be deferred temporarily until the congestion-inducing illness is resolved if nasal congestion will impede the delivery of the vaccine to the nasopharyngeal mucosa.

Available data indicate a very low risk for transmission of the virus in both children and adults vaccinated with LAIV. LAIV or TIV can be used to prevent influenza in those who are in close contact with most immunosuppressed individuals. Persons who are in contact with severely immunosuppressed individuals, such as those receiving care in a protective environment after undergoing hematopoietic stem cell transplantation, should not receive LAIV. For such individuals, TIV is recommended.

Severe allergic and anaphylactic reactions can occur in response to a number of influenza vaccine components, but such reactions are rare. All currently available influenza vaccines are prepared by means of inoculation of virus into chicken eggs. The use of influenza vaccines for persons with a history of egg allergy has been reviewed recently by the ACIP.[145] For the 2011-2012 influenza season, ACIP recommended that persons with egg allergy who report only hives after egg exposure should receive TIV, with several additional safety measures. Recent examination of VAERS data indicated no disproportionate reporting of allergy or anaphylaxis after influenza vaccination during the 2011-2012 season.[3] For the 2012-2013 influenza season, the ACIP recommended the following:

1. Persons with a history of egg allergy who have experienced only hives after exposure to egg should receive influenza vaccine, with the following additional safety measures (Fig. 244-5):
   a. Because studies published to date involved use of TIV, TIV rather than LAIV should be used.[342]
   b. Vaccine should be administered by a health care provider who is familiar with the potential manifestations of egg allergy.
   c. Vaccine recipients should be observed for at least 30 minutes for signs of a reaction after administration of each vaccine dose.[342]

   Other measures, such as dividing and administering the vaccine by a two-step approach and skin testing with vaccine, are not necessary.[342]

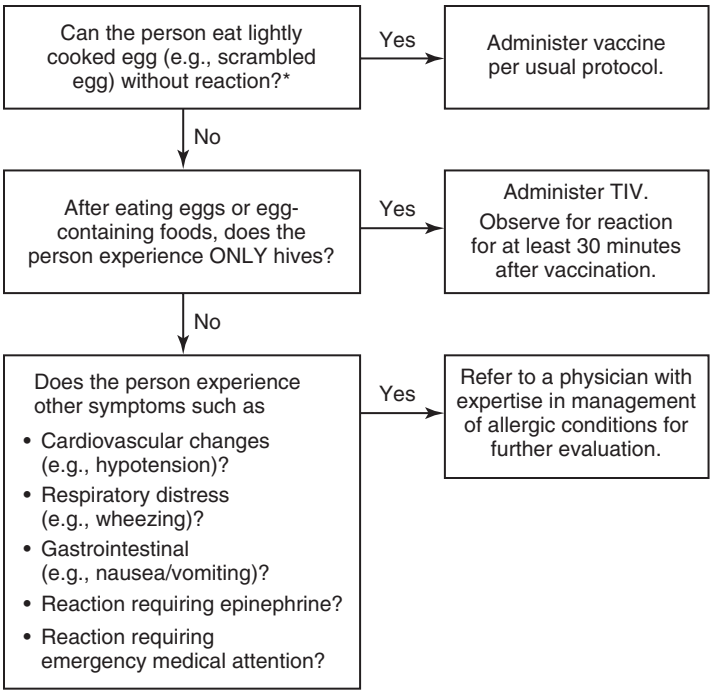

FIGURE 244-5 ■ Recommendations regarding influenza vaccination for persons who report allergy to eggs—Advisory Committee on Immunization Practices, United States, 2012-2013 influenza season. Persons with a history of egg allergy who have experienced only hives after exposure to egg should receive influenza vaccine, with the use of additional safety measures.
TIV, trivalent inactivated vaccine.
*Persons with egg allergy might tolerate egg in baked products (e.g., bread or cake). Tolerance to egg-containing foods does not exclude the possibility of egg allergy. (From Centers for Disease Control and Prevention. *Immunization schedules*. Available at http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6132a3.htm.)

2. Persons who report having had reactions to egg involving such symptoms as angioedema, respiratory distress, lightheadedness, or recurrent emesis or who required epinephrine or another emergency medical intervention, particularly those that occurred immediately or within a short time (minutes to hours) after egg exposure, are more likely to have a serious systemic or anaphylactic reaction on reexposure to egg proteins. Before receipt of vaccine, such persons should be referred to a physician with expertise in the management of allergic conditions for further risk assessment.

Measles Vaccine

Since the introduction of both an inactivated and a live virus, attenuated measles vaccine (Edmonston B strain) in the United States in 1963, the reported incidence of measles has decreased by more than 99 percent. Although the incidence of measles has declined in all age groups, the decline has been greatest in children aged 5 to 14 years.

Measles was targeted for elimination in the United States by 1982. Efforts to eliminate measles were not successful as a result of two factors. The first was vaccine failure. In the late 1980s, outbreaks occurred in older children in schools in which immunization rates usually were greater than 95 percent.[290,396,437] Attack rates were 1 to 5 percent because of the accumulation of measles-susceptible individuals from vaccine failure. The recurrent measles outbreaks among vaccinated school-aged children in the mid 1980s prompted both the ACIP and the AAP in 1989 to recommend that all children be given two doses of measles-containing vaccine, preferably as MMR.[34,97] Although administration of the second dose originally was recommended either at entry to primary school (ACIP) or middle/secondary school (AAP), the ACIP, the AAP, and the AAFP now recommend that a child be given the second dose at age 4 to 6 years rather than delaying it until the child is 11 to 12 years old.* The major benefit of administering the second dose is a reduction in the proportion of persons who remain susceptible because of primary vaccine failure. Waning immunity is not a major cause of vaccine failure and has little influence on transmission of measles, and revaccination of children who have low concentrations of measles antibody produces only a transient rise in antibody concentration.[392,395,401,448,557]

The second factor leading to outbreaks of measles was the failure to implement current immunization strategies, especially in the inner cities, where a high proportion of preschool-aged children had not been vaccinated. From 1989 through 1991, the proportion of unvaccinated persons with measles increased, as reflected by outbreaks among unvaccinated inner-city preschool-aged children. Multiple barriers to providing timely immunization to these children were identified during investigation of the measles resurgence that occurred between 1989 and 1991. Reported cases of measles declined rapidly after the 1989 to 1991 resurgence because of intensive efforts to vaccinate preschool-aged children. Measles vaccination levels among 2-year-old children increased from 70 percent in 1990 to 91 percent in 1997. From 2001-2008, a median of 56 measles cases were reported to the CDC annually.[451]

In 2000, the United States achieved measles elimination (defined as interruption of year-round endemic measles transmission).[339] However, importations of

*References 133, 392, 395, 398, 401, 448, 557.

measles into the United States continue to occur, posing risks for measles outbreaks and sustained measles transmission. Most cases are now imported from other countries or linked to imported cases. Most imported cases originate in Asia and Europe and occur among both U.S. citizens traveling abroad and persons visiting the United States from other countries. Since 1993, the largest outbreaks of measles in the United States have occurred in populations that refuse vaccination for religious or personal belief reasons. Most outbreaks have involved limited spread from measles imported from outside the United States.

During 2011, 222 cases of measles and 17 outbreaks were reported in the United States, an increase compared with cases and outbreaks reported during 2001 through 2010. Importations accounted for 32 percent of cases. Among patients who were U.S. residents, 85 percent were unvaccinated or had unknown vaccination status and were eligible for measles, mumps, and rubella vaccination.[131] The increased numbers of outbreaks and measles importations into the United States underscore the ongoing risk for measles among unvaccinated persons and the importance of vaccination against measles.

The recommended age for receiving routine vaccination with measles vaccine has been lowered in the past decade from 15 months to 12 to 15 months of age.[120] The decision to lower the age for receiving routine primary vaccination was based on the observation that most children are susceptible to measles by the time that they reach 12 months of age because of waning transplacental immunity.[385,393] Most mothers now have vaccine-induced immunity rather than immunity conferred by infection with wild virus. Antibody concentrations induced by measles vaccination generally are lower than those induced by natural measles. Therefore, measles-specific antibodies acquired transplacentally are lower in infants of vaccinated mothers, and these infants therefore are susceptible at an earlier age.

Preparations

The live measles virus vaccine (Moraten strain) available in the United States is prepared in chick fibroblast cell culture. Each dose of vaccine contains neomycin, sorbitol, and hydrolyzed gelatin as a stabilizer. Preparations include measles-mumps-rubella (MMR) and measles-mumps-rubella-varicella (MMRV) vaccines. MMRV vaccine was licensed in the United States in September 2005 and may be used instead of MMR and varicella vaccine to implement the recommended two-dose vaccine schedule for prevention of measles, mumps, rubella, and varicella among children aged 12 months to 12 years. Single-component measles vaccine is not available in the United States.

Inadequate protection against measles can result from the administration of improperly stored vaccine. Before reconstitution, measles vaccine must be stored at a temperature between 2°C and 8°C (35.6°F to 46.4°F) or colder and must be protected from light, which may inactivate the virus. Reconstituted vaccine should be stored in a refrigerator and discarded if not used within 8 hours.

Immunogenicity and Efficacy

Immunization produces a mild or inapparent, noncommunicable infection. Measles antibodies develop in approximately 95 percent of children vaccinated at 12 months of age and in 98 percent of children vaccinated at 15 months of age.[393] Studies indicate that serologic evidence of measles immunity develops in more than 99 percent of persons who receive two doses of measles vaccine, separated by at least 1 month, on or after their first birthday.[193,205] Although vaccine-induced antibody titers are lower than those after natural disease, persistence of protective titers for as long as 16 years after administration of vaccine has been demonstrated.[362,395] Most vaccinated persons who appear to lose antibody have an anamnestic response after revaccination, thus indicating that they most likely are still immune.[445] A small percentage of vaccinated individuals may lose protection after several years as a result of secondary vaccine failure.[401,594]

Adverse Events

Vaccine-associated symptoms, consisting of fever higher than 39.4°C (102.9°F) occurring 5 to 10 days after immunization or transient rash, develop in 5 to 18 percent of recipients.[370,457] Serious complications related to vaccine use occur far less frequently than after natural measles.[454]

Thrombocytopenia occurs at a rate of 1 case for every 30,000 to 40,000 doses distributed. Based on data from Sweden and Finland, the IOM concluded that a causal association exists between MMR and thrombocytopenia.[321] The decrease in platelet count presumably is caused by the measles component and usually is not clinically apparent. However, thrombocytopenic purpura occurring after vaccination has been reported.

Central nervous system disease, specifically encephalitis or encephalopathy, is reported at a rate of less than 1 case per 1 million doses of vaccine administered. Because the incidence of encephalitis or encephalopathy after the administration of measles vaccination to healthy children is lower than the observed incidence of encephalitis of unknown origin, some or most of the reported severe neurologic disorders may be only temporally, rather than causally, related to measles immunization. The risk for subacute sclerosing panencephalitis (SSPE) developing in vaccinated children is extremely low and is estimated to be approximately one twelfth the risk for SSPE developing after a case of natural measles (0.7 SSPE cases per million vaccine doses versus 8.5 cases per million natural measles infections).[80,102,321] Whether measles vaccine causes SSPE is unclear. Some cases of SSPE occur in children with no history of having measles or measles vaccination.[21]

Reactions to measles vaccine are not age related and occur only in susceptible vaccinees. After revaccination, reactions should be expected only in those who failed to respond to the first immunization.

To date, no convincing evidence establishes that any vaccine causes autism or autistic spectrum disorder. Concern has been raised about a possible relation between

MMR vaccine and autism by some parents of children with autism. Symptoms of autism often are noticed by parents during the second year of life and may manifest after administration of MMR by weeks or months. Two independent nongovernmental groups, the IOM and the AAP, have reviewed the evidence regarding a potential link between autism and MMR vaccine.[295,322,325] Both groups independently concluded that available evidence does not support an association and that the United States should continue its current MMR vaccination policy.

Indications

Unless otherwise contraindicated, measles vaccine is indicated for persons susceptible to measles.[21,133] The recommended age for receiving the first dose of measles vaccine is 12 to 15 months. In high-risk areas, such as those with recurrent measles transmission, the initial dose should be administered when the child reaches 12 months of age. The second dose is given routinely at 4 to 6 years and no later than 11 to 12 years of age. The minimal interval between the two doses is 4 weeks.

Adults born before 1957 generally may be considered immune to measles because of previous natural infection. Those born after 1956 and in whom immunoprophylaxis is indicated should receive two doses of vaccine.

During outbreaks, when the likelihood of exposure to measles is high, measles vaccine should be given to infants as young as 6 months. Seroconversion rates to vaccine are significantly less in children vaccinated before reaching 1 year of age than those in older children. Children immunized before their first birthday then should be revaccinated with MMR at 12 to 15 months of age, with a third dose given according to local policy.

Measles remains endemic in many areas of the world. Although vaccination against measles is not a requirement for entry into any country, susceptible children, adolescents, and adults born after 1956 should be offered measles vaccination (usually as MMR) before embarking on international travel. Infants 6 months or older who are traveling to areas where measles is endemic or epidemic should be vaccinated before departure and revaccinated at 12 to 15 months. Vaccination of infants younger than 6 months is not necessary because most young infants are protected by maternally derived antibodies.

Exposure of susceptible individuals to measles is not a contraindication to administering vaccination; vaccine given within 72 hours of exposure may provide protection. If exposure does not result in infection, immunization will protect against future infection.

MMRV vaccine may be used instead of MMR and varicella vaccine to implement the recommended two-dose vaccine schedule among children aged 12 months to 12 years. At the time of its licensure, use of MMRV vaccine was preferred for both the first and second doses over separate injections of equivalent component vaccines (MMR vaccine and varicella vaccine), which was consistent with the ACIP's 2006 general recommendations on use of combination vaccines.[359]

In February 2008, on the basis of preliminary data from two studies conducted post licensure that suggested an increased risk for febrile seizures 5 to 12 days after vaccination among children aged 12 to 23 months who had received the first dose of MMRV vaccine compared with children the same age who had received the first dose of MMR vaccine and varicella vaccine administered as separate injections at the same visit, ACIP issued updated recommendations regarding MMRV vaccine use.[176] These updated recommendations expressed no preference for use of MMRV vaccine over separate injections of equivalent component vaccines for both the first and second doses.

The final results of the two post-licensure studies indicated that among children aged 12 to 23 months, one additional febrile seizure occurred 5 to 12 days after vaccination per 2300 to 2600 children who had received the first dose of MMRV vaccine compared with children who had received the first dose of MMR vaccine and varicella vaccine administered as separate injections at the same visit.[349] Data from post-licensure studies do not suggest that children aged 4 to 6 years who received the second dose of MMRV vaccine had an increased risk for febrile seizures after vaccination compared with children the same age who received MMR vaccine and varicella vaccine administered as separate injections at the same visit.[350]

In June 2009, after consideration of the post-licensure data and other evidence, the ACIP adopted new recommendations regarding use of MMRV vaccine for the first and second doses and identified a personal or family (i.e., sibling or parent) history of seizure as a precaution for use of MMRV vaccine.[390] For the first dose of measles, mumps, rubella, and varicella vaccines at age 12 to 47 months, either MMR vaccine and varicella vaccine or MMRV vaccine may be used. Providers who are considering administering MMRV vaccine should discuss the benefits and risks of both vaccination options with the parents or caregivers. Unless the parent or caregiver expresses a preference for MMRV vaccine, the CDC recommends that MMR vaccine and varicella vaccine should be administered for the first dose in this age group. For the second dose of measles, mumps, rubella, and varicella vaccines at any age (15 months to 12 years) and for the first dose at age older than 48 months, use of MMRV vaccine generally is preferred over separate injections of its equivalent component vaccines (i.e., MMR vaccine and varicella vaccine). This recommendation is consistent with the ACIP's 2011 general recommendations regarding use of combination vaccines, which state that use of a combination vaccine generally is preferred over its equivalent component vaccines.[358]

Precautions and Contraindications

Immunocompromised patients with conditions such as lymphoreticular or other generalized malignant disease and primary or secondary immunodeficiency states should not be given live virus, attenuated measles vaccine.[21,133] After cessation of their chemotherapy, these individuals generally should not receive measles vaccine for at least 3 months. However, because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when

immunologic responsiveness will be restored, arriving at a definitive recommendation for an interval after cessation of immunosuppressive therapy when measles vaccine can be safely and effectively administered often is not possible.

An exception to the contraindication of administering measles vaccine to immunocompromised patients is asymptomatic HIV-infected patients, for whom measles vaccination, given as MMR at 12 to 15 months of age, is recommended. The need to protect HIV-infected persons who are at increased risk for having severe complications if infected with measles has been balanced against the risk for having adverse reactions. Measles vaccine is not recommended for HIV-infected persons with evidence of severe immunosuppression. A case of progressive measles pneumonitis occurred in a person with acquired immunodeficiency syndrome (AIDS) and severe immunosuppression to whom MMR vaccine was administered,[132] and morbidity related to measles vaccination has been reported in persons with severe immunosuppression unrelated to HIV infection. In addition, the antibody response to measles vaccine in severely immunocompromised HIV-infected persons is diminished.[57,71,402,418,421] In the United States, the incidence of measles currently is very low. Among HIV-infected persons who do not have evidence of severe immunosuppression, no serious or unusual adverse events have been reported after receiving measles vaccination.[407,443,449,512] Therefore, MMR vaccination is recommended for all asymptomatic HIV-infected persons who do not have evidence of severe immunosuppression and for whom measles vaccination would otherwise be indicated. MMR vaccination also should be considered for all symptomatic HIV-infected persons who do not have evidence of severe immunosuppression. Testing asymptomatic persons for HIV is not necessary before administering MMR.[48]

Systemically absorbed corticosteroids can suppress the immune system of an otherwise healthy person. However, neither the minimal dose nor the duration of therapy sufficient to cause immune suppression is well defined. Although the immunosuppressive effects of corticosteroid treatment vary, many clinicians consider that a corticosteroid dose equivalent to or greater than a prednisone dose of 2 mg/kg/day or a total of 20 mg/day is sufficiently immunosuppressive to raise concern about the safety of administering live virus vaccines. Persons who have received systemic corticosteroids in doses of 2 mg/kg/day or 20 mg daily or on alternate days for an interval of 14 days or longer should avoid receiving vaccination with MMR for at least 1 month after cessation of corticosteroid therapy.[133] Persons who have received prolonged or extensive topical, aerosolized, or other local corticosteroid therapy that causes clinical or laboratory evidence of systemic immunosuppression also should avoid receiving vaccination with MMR for at least 1 month after cessation of therapy.[133]

The live attenuated measles virus vaccine used for immunization is not communicable. Therefore, contacts of immunocompromised patients should be vaccinated to prevent the spread of natural measles to such patients.

Although no direct evidence has demonstrated that measles vaccine is harmful to a pregnant woman or her fetus, the vaccine should not be administered to women known to be pregnant or who are considering becoming pregnant because of the theoretical risk for fetal infection associated with a live virus vaccine. Women vaccinated with MMR should avoid conception for 28 days after being vaccinated.[138]

Because measles vaccination may diminish cutaneous manifestations of cell-mediated immunity temporarily, a tuberculin test performed several days to 6 weeks after receiving immunization can yield a false-negative result. Although natural measles infection can exacerbate tuberculosis, no evidence indicates that measles vaccination is associated with such an effect. Therefore, tuberculin skin testing is not a prerequisite for administering measles immunization. If a tuberculin test is indicated, it should be performed on the day of immunization or postponed for 4 to 6 weeks because measles vaccination may suppress tuberculin reactivity temporarily.

In persons allergic to eggs, the risk for having serious allergic reactions such as anaphylaxis after receiving MMR vaccine is extremely low, and skin testing with vaccine is not predictive of allergic reaction to vaccination.[21,330,344] Therefore, obtaining a skin test is not required before administering MMR to persons who are allergic to eggs. Similarly, the administration of gradually increasing doses of vaccine is not required.[133] Data indicate that most anaphylactic reactions to measles- and mumps-containing vaccines are not associated with hypersensitivity to egg antigens but to other components of the vaccines such as the gelatin stabilizer.[283,305,343,369]

Children with a previous history of thrombocytopenic purpura or thrombocytopenia may be at risk for developing clinically significant thrombocytopenia after receiving immunization with MMR.[68,321] The decision to vaccinate should be based on the benefits of immunity to measles, mumps, and rubella and the risk for recurrence or exacerbation of the thrombocytopenia after receiving vaccination or from natural infection with measles or rubella. For children in whom thrombocytopenia develops in the month after receiving a dose of measles-containing vaccine, withholding the second dose of measles vaccine is prudent if the incidence of measles remains low.

Receipt of antibody-containing blood products (whole blood, plasma, or parenteral immune globulin) may interfere with seroconversion to measles vaccine. High doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage.[506] The length of time that such passively acquired antibody persists depends on the concentration and quantity of the blood product received (Table 244-12).[21,359]

As with any condition that induces fever during the second year of life, children predisposed to having febrile seizures may experience seizures after receiving measles vaccination. Most convulsions that develop after receiving measles immunization are simple febrile seizures and occur in children without known risk factors. Febrile seizures that occur after the administration of vaccinations do not increase the risk for the subsequent development of epilepsy or other neurologic disorders.[66] An increased risk for having seizures after receiving measles

TABLE 244-12 **Suggested Intervals Between Immune Globulin Administration and Measles or Varicella Vaccination**

Product/Indication	Route	Dose		Interval (mo)*
		U or mL	mg/kg	
RSV monoclonal antibody (Synagis)	IM		15 (monoclonal)	None
Tetanus (as TIG)	IM	250 U	10	3
Hepatitis A prophylaxis (as IG)				
Contact prophylaxis	IM	0.02 mL/kg	3.3	3
International travel	IM	0.06 mL/kg	10	3
Hepatitis B prophylaxis (as HBIG)	IM	0.06 mL/kg	10	3
Rabies prophylaxis (as RIG)	IM	20 IU/kg	22	4
Varicella prophylaxis (as VariZIG)	IM	125 U/10 kg (maximum, 625 U)	20-40	5
Measles prophylaxis (as IG)				
Standard	IM	0.25 mL/kg	40	5
Immunocompromised contact	IM	0.50 mL/kg	80	6
Blood transfusion				
Washed RBCs	IV	10 mL/kg	Negligible	None
RBCs, adenine-saline added	IV	10 mL/kg	10	3
Packed RBCs	IV	10 mL/kg	20-60	5
Whole blood	IV	10 mL/kg	80-100	6
Plasma/platelet products	IV	10 mL/kg	160	7
CMV immune globulin	IV	3 mL/kg	150	6
IGIV				
Replacement therapy for immune deficiencies	IV		400	8
Therapy for ITP	IV		400	8
Therapy for ITP	IV		1000	10
Therapy for ITP or Kawasaki disease	IV		1600-2000	11

*These intervals should provide sufficient time for decreases in passive antibodies in all children to allow for an adequate response to measles or varicella vaccine. Physicians should not assume that children are fully protected against measles during these intervals. Additional doses of immune globulin or measles vaccine may be indicated after exposure to measles.

CMV, cytomegalovirus; HBIG, hepatitis B immune globulin; IG, immune globulin; IM, intramuscular; ITP, immune thrombocytopenic purpura; IV, intravenous; IGIV intravenous immune globulin; RIG, rabies immune globulin; RBCs, red blood cells; RSV, respiratory syncytial virus; TIG, tetanus immune globulin; VariZIG, varicella-zoster immune globulin.

vaccination may occur in children with a previous history of convulsions or those with a history of convulsions in first-degree family members.[550] Although the exact risk cannot be determined, it appears to be low. The recommendation to immunize children with a personal history of seizures or those with a history of seizures in first-degree family members is based on factors indicating that the benefits greatly outweigh the risks. Prophylactic use of anticonvulsants usually is not feasible because therapeutic concentrations of many currently prescribed anticonvulsants are not achieved for some time after the initiation of therapy.

Meningococcal Vaccine

Neisseria meningitidis has become a leading cause of bacterial meningitis in the United States after dramatic reductions in the incidence of *Streptococcus pneumoniae* and *H. influenzae* type b infections after the introduction of conjugate vaccines.[494,572] Meningococcal disease is fatal in 10 to 14 percent of cases. Of patients who recover, 11 to 19 percent have permanent hearing loss, mental retardation, loss of limbs, or other serious sequelae.

Disease most often occurs in children 2 years of age or younger; the peak incidence occurs in children younger than 1 year of age. Another peak occurs in adolescents and young adults 16 through 21 years of age. Historically, freshman college students who lived in dormitories and military recruits in boot camp had a higher rate of disease compared with persons who are the same age and who are not living in such accommodations. Close contacts of patients with meningococcal disease are at increased risk for becoming infected. Patients with persistent complement component deficiencies (e.g., C5 to C9, properdin, or factor H or factor D deficiencies) or anatomic or functional asplenia are at increased risk for invasive and recurrent meningococcal disease. Patients are considered capable of transmitting the organism for up to 24 hours after initiation of effective antimicrobial treatment. Asymptomatic colonization of the upper respiratory tract provides the source from which the organism is spread. Transmission occurs from person-to-person through

droplets from the respiratory tract and requires close contact.

The incidence of meningococcal disease varies over time and by age and location. During the past 60 years, the annual incidence of meningococcal disease in the United States has varied from 0.5 to 1.5 cases per 100,000 population. Incidence cycles have occurred over multiple years. Since the early 2000s, annual incidence rates have decreased and are sustained. The reasons for this decrease, which preceded introduction of meningococcal polysaccharide-protein conjugate vaccine into the immunization schedule, are not known but may be related to immunity of the population to circulating meningococcal strains and to the changes in behavioral risk factors (e.g., smoking).

Distribution of meningococcal serogroups in the United States has shifted in the past two decades. Serogroups B, C, and Y each account for approximately 30 percent of reported cases, but serogroup distribution varies by age, location, and time. Approximately three fourths of cases among adolescents and young adults are caused by serogroups C, Y, or W135 and potentially are preventable with available vaccines. In infants, 50 to 60 percent of cases are caused by serogroup B and are not preventable with vaccines available in the United States.

In other parts of the world, the number of cases is much higher.[110] In the sub-Saharan African "meningitis belt," which extends from Mali to Ethiopia, peaks of serogroup A meningococcal disease occur regularly during the dry season. In addition, major epidemics occur every 8 to 12 years. The last epidemic during 1996 to 1997 resulted in 213,658 cases, with 21,830 deaths. Meningococcal disease continues to cause epidemics outside the meningitis belt, including recent epidemics in the Great Lakes of Africa. Serogroup W135 has also emerged as an epidemic strain causing disease in Saudi Arabia in association with the Hajj pilgrimage in 2000, in Burkina Faso in 2002, and in several African countries in 2003 and 2004.

Preparations

Three meningococcal vaccines are licensed in the United States for use in children and adults against serotypes A, C, Y, and W135.

Quadrivalent meningococcal polysaccharide vaccine (MPSV4) was licensed in 1981 for use in children 2 years of age and older. Each vaccine dose contains 50 mg of each of the four purified bacterial capsular polysaccharides.[146] MPSV4 is available both as a single dose that is thimerosal free and in 10-dose vials that contain 25 µg of thimerosal/0.5 mL; 50-dose vials are no longer are available. MPSV4 is administered subcutaneously as a single 0.5-mL dose and can be given concurrently with other vaccines but at different anatomic sites.

Two meningococcal conjugate vaccines (MenACWY-D [Menactra, Sanofi Pasteur] and MenACWY-CRM [Menveo, Novartis Vaccines]) are licensed for use in persons 2 through 55 years of age. MenACWY-D is also licensed for infants as a two-dose primary series, 3 months apart, among children 9 through 23 months of age. Both meningococcal conjugate vaccines are administered intramuscularly as a single 0.5-mL dose and can be given concurrently with other recommended vaccines.

MenACWY-D is a liquid solution supplied in 0.5-mL single-dose vials. Each dose contains 4 µg each of the four capsular polysaccharides conjugated to 48 µg of diphtheria toxoid. The vaccine should be stored at 2°C to 8°C (35°F to 46°F).

MenACWY-CRM consists of two components: (1) 10 µg of lyophilized meningococcal serogroup A capsular polysaccharide conjugated to CRM197 (MenA) and (2) 5 µg each of capsular polysaccharide of serogroup C, Y, and W135 conjugated to CRM197 in 0.5 mL of phosphate buffered saline, which is used to reconstitute the lyophilized MenA component before injection. The vaccine should be stored at 2°C to 8°C (35°F to 46°F) prior to reconstitution. The reconstituted vaccine should be used immediately but may be held at or below 25°C (77°F) for up to 8 hours.

In June 2012, a combination conjugate vaccine against *H. influenzae* type b (PRP-T) and meningococcus serogroups C and Y (HibMenCY-TT, MenHibrix) was approved for children 6 weeks to 18 months. Recommendations for use of this vaccine are being considered.

No vaccine is available in the United States for prevention of serogroup B meningococcal disease, but clinical trials of several serogroup B vaccines are underway.

Immunogenicity and Efficacy

Polysaccharide Vaccine. Protective antibody concentrations are achieved within 10 to 14 days of administration of MPSV4. The vaccine elicits protective levels of bactericidal antibody to all four serogroups in more than 97 percent of recipients as measured at 28 days after vaccination. The antibody responses to each of the four polysaccharides in the polysaccharide vaccine are serogroup specific and independent. Group A polysaccharide induces antibody in some children as young as 3 months, although a response comparable to that in adults is not achieved until the child is 4 to 5 years of age.[459] The serum antibody response to serogroup C is age dependent, with a poor response in children younger than 2 years.[278] Serum concentrations of antibodies against group A and C polysaccharides decrease markedly during the first 3 years after receipt of a single dose of vaccine. The decrease in antibody occurs more rapidly in infants and young children than in adults.[341,590]

Field trials of A and C meningococcal vaccines in Europe and Africa have demonstrated efficacy rates against serogroup A of 85 to 95 percent 1 year after vaccination.[459,554] After 3 years, efficacy rates were 67 percent in older children but only 10 percent in children younger than 4 years old at the time of immunization with serogroup A vaccine.[471] In an epidemic, serogroup C vaccine demonstrated clinical efficacy rates similar to those of the serogroup A vaccine.[524]

Serogroup Y and W135 antigens are immunogenic and safe in children more than 2 years of age. However, clinical efficacy has not been demonstrated as yet for

these preparations.[7,56,552] Persons with deficiencies of the terminal components of serum complement and those with anatomic or functional asplenia have antibody responses to quadrivalent meningococcal vaccines consistent with protection.[483,485] However, the clinical efficacy of vaccination has not been evaluated in these persons.

Conjugate Vaccine. Protective antibody concentrations are achieved within 8 days after administration of MenACWY-D.[78] In studies conducted among persons aged 11 to 55 years comparing the immunogenicity of conjugate vaccine with that of the polysaccharide vaccine at 28 days after vaccination, the percentage of subjects achieving at least a fourfold increase in bactericidal titer for each serogroup was higher in the MPSV4 group than in the MenACWY-D group for persons older than 18 years of age. Nonetheless, the criteria for demonstrating immunologic noninferiority to MPSV4 were still achieved. The percentage of subjects with at least a fourfold rise was highest for serogroup W135 and lowest for serogroup Y. The percentage of subjects achieving a protective level of bactericidal antibody was greater than 97 percent for all serogroups in both MenACWY-D and MPSV4 groups.

Response to revaccination with MenACWY-D was assessed by administering MenACWY-D to subjects previously vaccinated with MPSV4 or MenACWY-D and to vaccine-naïve control subjects. All subjects in all three groups achieved protective bactericidal antibody titers at both 8 and 28 days after receiving MenACWY-D. Subjects initially primed with MenACWY-D achieved higher bactericidal antibody concentrations than those of naïve control subjects for all serogroups except A. In contrast, bactericidal antibody titers of those primed with MPSV4 were lower than those of vaccine-naïve control subjects on both days 8 and 28 for all serogroups.

In study participants aged 11 to 18 years, noninferiority of MenACWY-CRM to MenACWY-D was demonstrated for all four serogroups.[130] The proportions of subjects with seroresponse were statistically higher for serogroups A, W, and Y in the MenACWY-CRM group, compared with the MenACWY-D group. The clinical relevance of higher postvaccination immune responses is not known.

The immunogenicity of MenACWY-CRM in children aged 2 through 10 years was evaluated in a multicenter, randomized controlled trial.[294] After a single MenACWY-CRM dose, seroresponses to group C, Y, and W135 in children aged 2 through 5 years and 6 through 10 years were noninferior to responses after a single MenACWY-D dose.

MPSV4 is to be administered subcutaneously, whereas MCV4 is to be administered intramuscularly. More than 100 persons have inadvertently received the MCV4 vaccine by the subcutaneous route. For a subset of these individuals, the CDC determined that, although the serologic responses were lower after MCV4 was administered subcutaneously compared with intramuscularly, the proportions of individuals who achieved antibody levels thought to be protective were similar. Therefore, the CDC did not recommend that those who had received MCV4 needed to be reimmunized.[127]

Adverse Events

MPSV4 has been used extensively in mass-immunization programs as well as in the military and among international travelers. Adverse reactions to MPSV4 generally are mild; the most frequent reactions are pain and redness at the injection site that last for 1 or 2 days.[62] Estimates of the incidence of such local reactions have varied, ranging from 4 to 56 percent. Transient fever occurs in as many as 5 percent of vaccine recipients in some studies but is less common in older children and adults.

Among adolescents 11 to 18 years of age, safety of administering MCV4 and MPSV4 was assessed in two randomized, controlled trials. Common adverse reactions after MPSV4 and MCV4 immunization include localized pain, headache, and fatigue, all of which are mild and last for 1 to 2 days. Pain, induration, swelling, and redness at the injection site are slightly greater after administration of MCV4 compared with MPSV4. The frequency of local adverse reactions reported after MCV4 administration was similar to that reported after Td administration, which, like MCV4, is given intramuscularly. Fever is reported by 2 to 5 percent of adolescents who receive either MPSV4 or MCV4.[78]

Indications

Routine childhood immunization with meningococcal conjugate vaccines is not recommended for children 9 months through 10 years of age, because the infection rate is low in this age group; the immune response is less robust than in older children, adolescents, and adults; and duration of immunity is unknown.[35,154,161,181] However, a meningococcal conjugate vaccine is recommended for children and adolescents who are in high-risk groups as a two-dose series at 9 months through 55 years of age.[130,154]

Recommendations for use of a meningococcal conjugate vaccine are as follows:

- Adolescents should be immunized routinely at the 11- through 12-year of age health care visit, when immunization status and other preventive health services can be addressed. A booster dose at 16 years of age is recommended for adolescents immunized at 11 through 12 years of age.
- Adolescents 13 through 18 years of age should be immunized routinely with a meningococcal conjugate vaccine if not previously immunized. Adolescents who receive the first dose at 13 through 15 years of age should receive a one-time booster dose at 16 through 18 years of age.
- Adolescents who receive their first dose of meningococcal conjugate vaccine at or after 16 years of age do not need a booster dose unless they have risk factors.
- Persons at increased risk for invasive meningococcal disease should be immunized with meningococcal conjugate vaccine beginning at 9 months of age. Persons at increased risk include:
  - Children 9 months of age and older, including adults who have a persistent complement component deficiency (C5 to C9, properdin, factor H, or factor D).

  - Children 24 months of age or older including adults who have anatomic or functional asplenia. Because of high risk for invasive pneumococcal disease, children with functional or anatomic asplenia should not be immunized with MCV4-D (Menactra) before 2 years of age to avoid interference with the immune response to the PCV series.
  - Children with persistent complement component deficiencies who are vaccinated at 9 through 23 months of age should receive a two-dose primary series at least 8 weeks apart.
  - Children 9 through 23 months of age who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic should receive a two-dose primary series at least 8 weeks apart. Children 2 through 10 years of age who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic should receive one dose. Children who remain at increased risk should receive a booster dose 3 years later if the primary dose was given from 9 months through 6 years of age and 5 years after the last dose if the previous dose was given at 7 years of age or older.*
  - Military recruits.
- Because persons with HIV infection are likely to be at higher risk for meningococcal disease, although not to the extent that they are at risk for invasive *S. pneumoniae* infection, they may be immunized with a meningococcal conjugate vaccine (MCV4). Persons with HIV infection who are 2 years of age or older should receive a 2-dose primary series at least 8 weeks apart.
- Persons, including parents of children who wish to decrease their risk for meningococcal disease, may elect to receive MCV4 if they are 9 months of age or older.
- For control of meningococcal outbreaks caused by vaccine-preventable serogroups (A, C, Y, or W135), MCV4 should be used for persons 9 months through 55 years of age. MPSV4 should be used for persons older than 55 years of age in outbreak situations.
- Immunization with MCV4 is preferred for children previously immunized with MPSV4 if at least 3 years have elapsed since receiving MPSV4.

Reimmunization

Children previously immunized with either MCV4 or MPSV4 who are at prolonged increased risk for meningococcal disease should be reimmunized with MCV4. In children 2 through 6 years of age, MCV4 should be given as a booster dose 3 years after initial immunization, because concentrations of bactericidal antibodies against serogroups in the vaccine after the first dose are unlikely to provide continued protection for these children at high risk. In children 7 through 10 years of age and in adolescents who have received either MCV4 or MSPV4, a booster dose of an MCV4 is recommended 5 years after the first dose. For children recommended to receive a two-dose primary series, a booster dose of an MCV4 is recommended 5 years after the primary series regardless of the child's age when the primary series was given.

Postexposure Immunoprophylaxis

Because secondary cases can occur several weeks or more after onset of disease in the index case, meningococcal vaccine is an adjunct to chemoprophylaxis when an outbreak is caused by a serogroup prevented by a meningococcal vaccine. For control of meningococcal outbreaks caused by vaccine-preventable serogroups (A, C, Y, and W135), the preferred vaccine in adults and children 2 years of age and older is a meningococcal conjugate vaccine.

Precautions and Contraindications

Because of theoretical considerations, meningococcal polysaccharide vaccines should not be administered to pregnant women unless the risk for acquiring disease is substantial. However, evaluation of pregnant women immunized during an epidemic in Brazil demonstrated no adverse effects.[405]

Immunization with MCV4 is contraindicated among persons known to have hypersensitivity to any component of the vaccine, including diphtheria toxoid, and to dry, natural rubber latex, which is used in the vial stopper. Because of the temporal association between MCV4 and Guillain-Barré syndrome, MCV4 should not be given to adolescents or adults with a history of Guillain-Barré syndrome who are not in a high-risk group for developing invasive meningococcal disease.

Mumps Vaccine

Live virus mumps vaccine became available in the United States in 1967 and was recommended for routine use in 1977. After vaccine licensure, the incidence of reported mumps cases decreased rapidly. A relative resurgence of mumps occurred in 1986 and 1987. In 1989, the ACIP and AAP implemented a two-dose combined MMR schedule given either at 4 to 6 or at 11 to 12 years of age. After implementation of the two-dose MMR vaccination requirement, the incidence of mumps disease decreased and reached a record low of 258 cases in 2004.[165] Before vaccine licensure in 1967 and during the early years of vaccine use, most reported cases occurred in the 5- to 9-year age group; 90 percent of cases occurred among children 15 years of age and younger. In the late 1980s, a shift toward older children occurred. Since 1990, persons age 15 years and older have accounted for 30 to 40 percent of cases per year.

Between January and October of 2006, more than 5700 confirmed or probable mumps cases were reported, predominantly among patients aged 18 to 24 years, many

*CDC Travelers' Health Hotline 877-FYI-TRIP or online at www.cdc.gov/travel.

of whom were college students. Twelve Midwestern states were most affected, but sporadic cases were documented in many other states, mostly related to travel from primary outbreak areas. Nearly half of all cases occurred in Iowa, where the resurgence began.[108] The 2006 outbreak underscored limitations in the 1998 recommendations relating to prevention of mumps transmission in health care and other settings with high risk for mumps transmission. After reviewing data from this outbreak and previous evidence on mumps vaccine effectiveness and transmission, the ACIP issued updated recommendations for mumps vaccination.[139] In the following 2 years, the number of reported cases returned to usual levels and outbreaks involved fewer than 20 cases.

Another outbreak in 2009-2010 affected more than 3500 persons, primarily members of traditional observant communities in New York and New Jersey.[174] Because two doses of mumps-containing vaccine are not 100 percent effective, in settings of high immunization coverage such as the United States, most mumps cases likely will occur in persons who have received two doses.

Preparations

The live attenuated mumps virus vaccine (Jeryl Lynn strain) in current use in the United States is prepared in chick embryo cell culture and is available in combination as MMR and MMRV. The AAP and ACIP recommend that combined MMR vaccine be used when any of the individual components is indicated and MMRV is recommended if the vaccinee is 12 months through 12 years of age.

Each dose of vaccine contains neomycin, sorbitol, and hydrolyzed gelatin as stabilizers. Before reconstitution, MMR vaccine must be stored at 2° C to 8° C (35.6° F to 46.4° F) or colder and protected from light to avoid inactivation. After reconstitution, the vaccine should be used within 8 hours or discarded.

Immunogenicity and Efficacy

The vaccine induces an asymptomatic, noncommunicable infection. More than 97 percent of susceptible recipients develop protective antibody titers, albeit lower than those after natural infection.[565] Post-licensure studies in the United States demonstrated that one dose of mumps vaccine was 78 to 91 percent effective in preventing clinical mumps with parotitis.[466] Studies of vaccine effectiveness during outbreaks suggested substantially higher levels of protection with a second dose of MMR.[85,300,458]

The effectiveness of the mumps component of MMR vaccine was estimated during the large outbreak in the United Kingdom in 2004 to 2005. Vaccine effectiveness was 88 percent for one dose and 95 percent for two doses. The effectiveness of one dose declined from 96 percent in 2-year olds to 66 percent in 11- to 12-year olds, and the effectiveness of two doses declined from 99 percent in 5- to 6-year olds to 86 percent in 11- to 12-year olds.[203] The duration of vaccine immunity is unknown, but serologic data showed persistence of antibody for more than 30 years.[563] However, data from more recent studies suggested that waning immunity may contribute to mumps outbreaks in older vaccinated populations.[203]

Adverse Events

The use of mumps vaccine is associated with very few side effects. Parotitis and fever have been reported rarely. Hypersensitivity reactions, including rash, pruritus, and purpura, have been associated temporally with vaccination, but they are transient and generally mild. Administration of MMR is not harmful if it is given to an individual already immune to one or more of the viruses.[22,133]

The frequency of reported central nervous system dysfunction after vaccination is not greater than the observed background rate in unimmunized persons.[133] The IOM concluded that evidence is inadequate to establish a causal relationship between the Jeryl Lynn strain of mumps vaccine used in the United States and aseptic meningitis, encephalitis, or sensorineural deafness.[321]

Indications

Routine active immunization as MMR in children 12 to 15 months of age is recommended.[22,108,133] Most children will receive a second dose of mumps vaccine in childhood as a result of the recommendation for routine measles revaccination with MMR. Susceptible older children, adolescents, and adults also should be vaccinated against mumps.

Evidence of immunity through documentation of vaccination is now defined as one dose of live mumps vaccine for preschool-aged children and adults not at high risk for exposure and infection and two doses of live mumps vaccine for school-aged children (i.e., grades kindergarten to 12) and adults at high risk for exposure and development of infection (i.e., health care workers, international travelers, and students at post–high school education institutions). Additional recommendations for outbreak control include administering a second dose of MMR for preschool-aged children and adults not at high risk for exposure and acquisition of infection if these persons are part of a group that is experiencing an outbreak.[108] To ensure high levels of immunity, especially among groups at high risk for exposure and development of infection, every opportunity should be used to provide the first or second dose of MMR vaccine to those without adequate evidence of immunity (e.g., documentation of vaccination).

Mumps remains endemic throughout most of the world. Although vaccination against mumps is not a requirement for entry into any country, susceptible children, adolescents, and adults born after 1956 should be offered mumps vaccination, usually as MMR, before engaging in international travel.

Mumps vaccine is of no proven value in the prevention of disease in susceptible individuals after exposure to mumps, probably because the time required to develop protective antibody titers after immunization exceeds the incubation period of clinical mumps. However, if the exposure does not result in infection, the vaccine confers subsequent immunity.

Precautions and Contraindications

Among persons who are allergic to eggs, the risk for having serious allergic reactions such as anaphylaxis after receiving MMR is extremely low and skin testing with vaccine is not predictive of allergic reaction to vaccination.[22,330,344] Therefore, performing skin testing is not required before administering MMR to persons who are allergic to eggs. Similarly, the administration of gradually increasing doses of vaccine is not required.[133] Data indicate that most anaphylactic reactions to measles- and mumps-containing vaccines are not associated with hypersensitivity to egg antigens but rather with hypersensitivity to other components of the vaccines, such as the gelatin stabilizer.[283,305,343,369]

Because of the theoretical risk for fetal damage, mumps vaccine should not be administered to women known to be pregnant or who are considering becoming pregnant. Women vaccinated with MMR should avoid conception for 28 days after vaccination.[138]

Lymphoreticular or other generalized malignancy and primary or secondary immunodeficiency states represent contraindications to the use of mumps vaccine. Exceptions are children with HIV infection who are immunized against measles with MMR (see Measles Vaccine). Because infection after vaccination is noncommunicable, susceptible close contacts of immunosuppressed patients should be vaccinated to avoid exposure to mumps in such patients.

After cessation of immunosuppressive therapy, live virus mumps vaccine generally is withheld for at least 3 months. Because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when immunologic responsiveness will be restored, making a definitive recommendation for an interval after cessation of immunosuppressive therapy when mumps vaccine can be safely and effectively administered often is not possible.

The effect of immune globulin preparations on the response to mumps vaccine is unknown. High doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage.[22] If mumps vaccine is given as the MMR vaccine, the recommendations for measles vaccine should be followed (see Table 244-12).

Administration of mumps vaccine should be avoided if the individual is receiving immunosuppressive dosages of systemic corticosteroids. The effects of corticosteroids vary, but many clinicians consider that a dose equivalent to either 2 mg/kg/day or 20 mg/day of prednisone is sufficiently immunosuppressive to raise concern about the safety of vaccination with live virus vaccines.

Pertussis Vaccine

Pertussis (whooping cough), caused by the fastidious, gram-negative, pleomorphic bacillus *B. pertussis*, continues to produce significant morbidity and mortality worldwide among young children.[428] In the absence of vaccination, the WHO estimated that approximately 1 million deaths would have occurred from the disease and its complications. In the United States, the number of cases has been reduced by approximately 95 percent during the vaccine era. Despite an effective vaccine, however, pertussis continues to occur in the United States in all age groups. Since the historic low point achieved in the 1980s, the incidence of pertussis has increased steadily. Surveillance data collected by the CDC's National Immunization Program for the periods from 1994 through 1996 and 1997 through 2000 demonstrated that the incidence of pertussis increased 60 percent in adolescents and adults and 11 percent in infants younger than 6 months.[141] Data from the National Notifiable Disease Surveillance System reveal an escalation in the increase in all age groups between 2001 and 2004.[86] Incidence rates among the pediatric population peak in infants younger than 6 months of age and again during adolescence between 11 and 18 years of age.[39] The increase in the number of cases among young infants suggests that a true increase in pertussis circulation has occurred. The number of cases in children old enough to receive vaccine has remained stable. The likely reason that pertussis remains endemic in the United States despite high vaccination rates is that neither infection nor immunization provides life-long immunity. Humans are the only known reservoir for pertussis; immunity wanes after 5 to 10 years, thus maintaining a population of susceptible hosts for the continued circulation of bacteria.

The experiences of countries where rates of pertussis vaccination have markedly declined provide strong support for continuing routine immunization of infants and young children.[192] In the United Kingdom, as a result of adverse publicity about pertussis vaccination, a decrease in immunization rates in 2-year-old children from 77 percent in 1974 to 30 percent in 1978 was followed by an epidemic of 102,500 cases of pertussis. A similar experience occurred in Japan, which reported 13,105 cases and 41 deaths in 1979 after routine immunization had been suspended temporarily in 1975.

In the United States during the 1980s, publicity about alleged serious reactions to pertussis vaccine generated public controversy about the risk for receiving pertussis vaccine that resulted in costly litigation and escalating vaccine costs and also jeopardized vaccine supply and development.[427,460] The experience in countries such as England and Japan, the severity of pertussis in young infants, and the usually benign or self-limited sequelae of pertussis vaccination clearly justify continuing routine childhood immunization. Several risk-to-benefit analyses provided additional evidence in support of vaccination.[192,310]

Effective primary preventive programs necessitate immunizing young infants, usually beginning at 2 months of age, because the morbidity and mortality of pertussis are greatest in infants, especially those younger than 6 months.[142,192] Approximately 26 percent of reported cases in the United States occur in infants younger than 6 months. During the period from 1997 through 2000, the case-fatality rate for infants younger than 6 months was 0.8 percent; 63 percent of these infants were hospitalized with frequent complications, including pneumonia (11.8 percent), seizures (1.4 percent), and encephalopathy (0.2 percent).[141] From 2000 through 2004, 100

pertussis-related deaths were reported; 90 percent were among infants younger than 4 months of age and 76 percent occurred in infants younger than 2 months of age.[86] Maintaining high rates of immunization in children beyond infancy, with booster immunization for adolescents and adults, may reduce the risk for infection in infants by decreasing the incidence of infection in older family members and the resultant transmission of *B. pertussis* within the household. Vaccination, including boosters, is essential because the disease is highly infectious and transmission often occurs before adults seek medical care.

Preparations

Whole-cell pertussis vaccine was introduced first in the United States in the 1920s. Not until the 1940s to 1950s, however, did pediatric whole-cell pertussis vaccine became routinely recommended for children. This vaccine, unavailable in the United States since 2002, consisted of a suspension of inactivated *B. pertussis* combined with diphtheria and tetanus toxoids (DTP).[86] To reduce the incidence of local and systemic reactions caused by whole-cell vaccines, less reactogenic pediatric acellular vaccines composed of one or more purified components of *B. pertussis* combined with diphtheria and tetanus toxoids (DTaP) were developed. Initially licensed in 1991 for use as the fourth or fifth dose in the series, DTaP was licensed in 1997 for all five doses in the series. Numerous acellular vaccines formulated from the different components have been tested in children. All currently U.S. licensed vaccines contain detoxified/inactivated pertussis toxin (i.e., pertussis toxoid) and filamentous hemagglutinin.[227] In addition, most vaccines include one or both of the following *B. pertussis* antigens: pertactin (PRN, a 69-kDa outer-membrane protein) and fimbriae proteins (FIM, agglutinogens). The various vaccines differ in the amount of each component. No pertussis-only vaccine is available.

From 2001 until 2008, numerous changes were made to the list of licensed acellular pertussis–containing vaccines available in the United States. Three acellular vaccines currently are available for use in the primary vaccination series for children younger than 7 years of age (Table 244-13). Tripedia (Sanofi Pasteur), Daptacel (Sanofi Pasteur), and Infanrix (GlaxoSmithKline Biologicals) are licensed for the five-dose DTaP vaccination series. Pediarix (GSK), which combines DTaP with IPV and HBV vaccines, was licensed in 2002 for the first three doses in the DTaP series for use in children 6 weeks to 6 years old and born to mothers known to be HBsAg negative. This vaccine is not approved for the first HBV vaccine, for the fourth or fifth DTaP dose, or for infants born to women known to be HBsAg positive or whose hepatitis B status is unknown. TriHIBit (Sanofi Pasteur), the combination of Tripedia and ActHIB (Hib conjugate vaccine), was licensed by the FDA in 2001 for use as the fourth booster dose given when the infant is 15 to 18 months of age and not for use as part of the initial three-dose series. Pentacel (Sanofi Pasteur), which combines DTaP with IPV and Hib (PRP-T) vaccines, was licensed in 2008 for the first four doses in the DTaP series in children 6 weeks to 6 years of age. Kinrix (GSK), a combination of DTaP with IPV, was also licensed in 2008 for use for the fifth dose of DTaP in children 4 to 6 years of age.

For enhanced control of pertussis, routine revaccination of adolescents and adults with an acellular pertussis vaccine is now recommended to minimize the morbidity associated with infection in these age groups and to reduce the reservoir of infection. In 2005, the FDA licensed two Tdap vaccines (see Table 244-13); Boostrix (GSK) is approved for persons aged 10 years and older, and Adacel (Sanofi Pasteur) is approved for adolescents and adults aged 11 to 64 years. Both Tdap vaccines contain the same pertussis antigen components as are in the pediatric vaccines (some in reduced quantities). The tetanus and diphtheria components are the same as for the current adult formations of Td, with reduced diphtheria content as recommended for use in persons 7 years of age and older.

The ACIP recommends that, whenever feasible, the same DTaP vaccine product be used for all doses of the vaccination series. If the vaccine provider does not know or does not have available the type of DTaP previously administered, any of the available licensed DTaP vaccines may be used to complete the vaccination series.[185]

Immunogenicity

The Multicenter Acellular Pertussis Trial evaluated the immunogenicity and safety of 13 different acellular pertussis–containing vaccines as compared with whole-cell DTP administered to infants at 2, 4, and 6 months

TABLE 244-13 **Acellular Pertussis Vaccines Licensed for Use in the United States**

Trade Name	Vaccine Manufacturer	No. of Pertussis Antigens	Antigenic Content	Dose Series Approved
DTaP Vaccines for Children <7 Yr				
Tripedia	Sanofi Pasteur	2	PT, FHA	5
Infanrix	GlaxoSmithKline Biologicals	3	PT, FHA, PE	5
DAPTACEL	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	5
Tdap Vaccines for Adolescents				
BOOSTRIX	GlaxoSmithKline Biologicals	3	PT, FHA, PE	1
ADACEL	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	1

DTaP, diphtheria–tetanus–acellular pertussis; FHA, filamentous hemagglutinin; FIM, fimbriae; PE, pertactin; PT, pertussis toxin; Tdap, tetanus–diphtheria–acellular pertussis.

of age in the United States.[227] Serologic correlates of immunity to diphtheria and tetanus toxoids, defined as antibody levels 0.1 IU/mL or greater, were achieved after vaccination with Tripedia and Infanrix and were comparable with those achieved with DTP vaccination. Pertussis immunity, determined by at least a fourfold rise in antibody titer to pertussis toxin and filamentous hemagglutinin, was equal to or greater than with DTP, after immunization with either of the two DTaP vaccines.[244]

Efficacy

For both whole-cell and acellular vaccines, serologic correlates of immunogenicity have not been established for assessing efficacy. As a result, field and other epidemiologic studies must be performed to demonstrate efficacy. Studies in the United States of household contacts exposed to pertussis indicate that the efficacy of whole-cell vaccine was 80 percent or greater.[142,192,444] Studies reporting lower rates of vaccine efficacy often reflect the use of different criteria for the diagnosis of pertussis and lesser effectiveness of the vaccine in protecting against mild infection than against severe disease.[253] Vaccine-induced immunity persists for at least 3 years and subsequently diminishes with time. Pertussis in individuals previously vaccinated is less severe and is associated with fewer complications than in unvaccinated persons.

In studies of the efficacy of eight acellular pertussis vaccines in infants, rates of prevention of pertussis ranged from 58 to 93 percent.[465] Comparing efficacy among the different products, however, often is not possible because of differences in study design, vaccine schedule (specifically, the number of doses and age of administration), case definitions of pertussis, and other confounding variables. In general, these acellular vaccines appear to be similar in efficacy to most whole-cell vaccines. Whereas in two large trials in Sweden and Italy several acellular vaccines demonstrated substantially greater efficacy than noted in the one U.S. whole-cell vaccine previously approved, other whole-cell vaccines studied appeared to be slightly more effective than were acellular vaccines in other trials.[243] In addition, the vaccines in these Swedish and Italian trials were given in a three-dose schedule, in contrast to the four-dose primary schedule for vaccination of young children in the United States.

Adverse Events

Local and febrile reactions to whole-cell vaccines occur in more than half of DTP recipients.[202] These manifestations usually develop within the first 24 hours and are brief in duration. More serious reactions to whole-cell vaccines are uncommon. Such reactions include prolonged crying for 3 hours or longer occurring within the first 48 hours of receiving vaccination (1 to 3 percent of DTP recipients) and a temperature of 40.5° C or greater (≥104.9° F) within 48 hours (0.3%); a hypotonic-hyporesponsive episode described as collapse or shock-like state within 48 hours and seizure within 3 days of vaccination each was estimated to occur once per 1750 doses.[202] Episodes of inconsolable crying, high fever, and hypotonic-hyporesponsive episodes after receipt of DTP vaccine resolved without sequelae. Most post-DTP seizures occurring within 48 hours of receipt of vaccine are brief, self-limited, and generalized and occur in association with fever. These seizures have not been demonstrated to result in the subsequent development of epilepsy or other neurologic sequelae. Predisposing factors include an underlying convulsive disorder, a personal history of previous convulsion, and a family history of convulsions.[180]

The incidence of local and febrile reactions after the administration of acellular vaccines is significantly lower.[227,465] Comparison of rates of adverse events with different acellular vaccines compared with whole-cell vaccines demonstrated similar safety profiles for each of these vaccines.[195,493] The most common adverse events include injection site reactions (erythema, induration, tenderness) and the following mild system symptoms: slight to moderate fever, drowsiness, irritability, and loss of appetite. Rates of local reactions increase with each subsequent dose of DTaP vaccine.[463,530] Booster doses of acellular pertussis vaccine may be associated with extensive local swelling (i.e., limb swelling), especially with vaccines having a high diphtheria content.[472] The pathogenesis of this reaction is not understood but spontaneously resolves without sequelae and is not associated with an increased risk for similar adverse events occurring after receipt of the fifth dose.[23] Severe reactions to acellular vaccines such as prolonged crying of 3 hours or more, temperature greater than or equal to 40.5° C (104.9° F), hypotonic-hyporesponsive episodes, and seizures are rare.* As with local and febrile reactions, their occurrence with acellular pertussis vaccination is significantly less frequent than that after whole-cell vaccination.

Syncope can occur after immunization with Tdap, is more common among adolescents and young adults, and can result in serious injury if a vaccine recipient falls. Vaccinees should be seated and observed for 15 minutes after immunization. If syncope occurs, patients should be observed until symptoms resolve.[23]

Serious Neurologic Illness. The National Childhood Encephalopathy Study (NCES), a large case-control study from Great Britain that was published in 1985, estimated that the occurrence of acute neurologic illness resulting in hospitalization was 1 in 140,000 DTP vaccinations.[416] In a 10-year follow-up study published in 1993, neurologic sequelae were found to be common occurrences, but no more so than in children with unrelated, acute neurologic illness in infancy,[415] and reviews of the data have disputed the conclusion that pertussis vaccine can cause neurologic sequelae.[47,180,518] More recent data from Canada evaluating more than 12,000 pediatric hospitalizations for serious neurologic illness between 1993 and 2002 found no association after administration of more than 6.5 million doses between development of encephalopathy and receipt of DTaP vaccination.[24] Taken together, the data do not support a role for whole-cell pertussis vaccine in causing brain damage.[95]

*References 195, 227, 280, 290, 465, 493, 532.

Indications

Vaccination against pertussis with DTaP is recommended routinely for children at 2, 4, and 6 months of age, followed by a fourth dose at 12 to 18 months of age and a fifth dose at 4 to 6 years of age.[24,39,86] Immunization can be started when the child is as young as 6 weeks of age if pertussis is prevalent in the community. The interval between administrations of the three doses of the initial series can be as short as 4 weeks. The AAP and ACIP recommend exclusive use of acellular pertussis vaccines for all doses of the pertussis vaccine series.[24,39,86] DTP is no longer available in the United States. However, in many countries, including several in Europe as well as in developing countries, whole-cell vaccine remains the recommended product.

A single dose of Tdap is recommended universally for persons 11 years of age and older, including adults, in place of the initial Td booster vaccine. The preferred schedule is to administer Tdap at the 11- or 12- year-old preventive visit, for those who have completed their primary DTP/DTaP series.[24,39,86] Adolescents and adults 11 years of age and older who received Td but not Tdap should receive a single dose of Tdap to provide protection against pertussis. Tdap can be administered regardless of time since receipt of last tetanus- or diphtheria-containing vaccine.[23] Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis should initially receive a single dose of Tdap followed by Td for the subsequent two doses at 4 weeks or more and 6 to 12 months later. No pertussis-containing vaccine is FDA approved for children between the ages of 7 and 10 years. If pertussis vaccine is not contraindicated, children aged 7 through 10 years who are not fully vaccinated (have not received five doses of DTaP or four doses of DTaP if the fourth dose was administered on or after the fourth birthday) should receive a single dose of Tdap to provide protection against pertussis. If additional doses of tetanus and diphtheria toxoid–containing vaccines are needed for children aged 7 through 10 years, Tdap vaccine is substituted as the first dose. The subsequent two doses should be Td vaccine at 4 weeks or more and 6 to 12 months after the previous dose if indicated for the catch-up series.[9,86]

Women should receive Tdap before becoming pregnant. Women who have not been immunized previously with Tdap should receive Tdap during pregnancy, preferably during the third or late-second trimester (after 20 weeks' gestation); or if it is not administered during pregnancy, Tdap should be administered in the immediate postpartum period.[183] Every 10 years thereafter, booster vaccination should be provided by Td.

As further protection against transmission of pertussis to infants who are at greatest risk for pertussis-related morbidity or mortality compared with other age groups, the cocoon strategy is recommended to immunize mothers, families, and close contacts against pertussis to decrease their likelihood of acquisition and subsequent transmission of *B. pertussis* to young infants. Adolescents and adults (e.g., parents, siblings, grandparents, child-care providers, and health care personnel) who have or anticipate having close contact with an infant younger than 12 months of age should receive a single dose of Tdap to protect against pertussis if they have not previously received Tdap. Ideally, these persons should receive Tdap at least 2 weeks before beginning close contact with the infant.[23,183]

Contraindications and Precautions

The contraindications and precautions for administering pertussis vaccine are based on adverse reactions associated with whole-cell vaccine. Although reactions occurring after the administration of DTaP are much less common than are those associated with DTP, at present the contraindications and precautions for DTaP are the same.[24,39,86] Adverse events temporally related to pertussis immunization that contraindicate further administration of DTaP are as follows:

- An immediate anaphylactic reaction. Subsequent immunization with any of the three components of the vaccine should be avoided.
- Encephalopathy occurring within 7 days. Children who experienced encephalopathy within 7 days after administration of a previous dose of diphtheria and tetanus toxoids and pertussis vaccine (DTP, DTaP, or Tdap) not attributable to another identifiable cause should not receive additional doses of a vaccine that contains pertussis. Encephalopathy in this context is defined as a severe, acute, central nervous system disorder (e.g., coma or prolonged seizures) unexplained by another cause and may be manifested by major alterations in consciousness or by generalized or focal seizures that persist for more than a few hours without recovery within 24 hours. Additional doses of DT (or Td) vaccine should be substituted for any pertussis-containing vaccine.

Post-vaccination reactions constituting precautions are as follows:

- Presence of a moderate or severe acute illness with or without a fever
- Guillain-Barré syndrome within 6 weeks after a previous dose of tetanus toxoid containing vaccine
- A convulsion, with or without fever, occurring within 3 days of receiving DTP or DTaP vaccination
- Persistent, severe, inconsolable screaming or crying for 3 hours or more within 48 hours of DTP or DTaP vaccination
- Hypotonic-hyporesponsive episode occurring within 48 hours of DTP or DTaP vaccination
- Temperature of 40.5° C (104.9° F) or greater that is unexplained by another cause and occurs within 48 hours of DTP or DTaP vaccination

With these adverse events occurring in temporal association with DTaP vaccination, the decision to administer additional doses of pertussis vaccine should be considered carefully. Children for whom vaccination is deferred because of moderate or severe acute illness should be vaccinated when their condition improves. In circumstances such as a pertussis outbreak in which the potential benefits of pertussis immunization outweigh the possible risks, vaccination is indicated, particularly because these events have not been proved to cause permanent sequelae.

In addition, the risk for these reactions occurring after receipt of DTaP is substantially lower than after receipt of DTP.

In children with an evolving neurologic disorder in the first year of life, pertussis immunization should be deferred until the nature and cause of the disorder have been established. A personal history of having a stable neurologic condition (previous convulsion unrelated to DTaP vaccination, a history of seizure disorder, well-controlled seizures, cerebral palsy) or a family history of convulsions is not a contraindication, and pertussis immunization should be administered on schedule.

As noted earlier, certain conditions after DTaP vaccine, such as temperature of 40.5 C (104.9° F) or higher, collapse or shock-like state, persistent crying, or convulsions with or without fever are a precaution to subsequent doses of DTaP. However, occurrence of one of these adverse reactions after DTaP vaccine in childhood is not a contraindication or precaution to administration of Tdap to an adolescent or adult. A history of severe Arthus hypersensitivity reaction after a previous dose of a tetanus or diphtheria toxoid–containing vaccine administered less than 10 years previously should lead to deferral of Tdap or Td immunization for 10 years after administration of the tetanus or diphtheria toxoid–containing vaccine.[23,86]

Pneumococcal Vaccine

S. pneumoniae is a leading bacterial pathogen, especially among young children, elderly persons, and persons with predisposing conditions. In children, it is the most common cause of otitis media, occult bacteremia, and bacterial pneumonia requiring hospitalization. After the widespread introduction of conjugate Hib vaccination and subsequent marked decline in occurrence of *H. influenzae* type b meningitis, *S. pneumoniae* became a leading cause of bacterial meningitis in children in the United States. In some populations, such as Alaska Natives, the incidence of bacteremia is markedly higher than that reported in other geographic areas of the United States.[225] Groups considered at high risk for invasive pneumococcal disease (IPD) include children with sickle-cell disease, asplenia, Hodgkin disease, congenital humoral immunodeficiency, HIV infection, and nephrotic syndrome, as well as recipients of organ transplants. Children who have received cochlear implants are at particular risk for developing meningitis.[143,470] Other chronic diseases associated with an increased risk for development of severe pneumococcal disease include chronic cardiovascular and pulmonary diseases, diabetes mellitus, and renal failure. The role of these chronic diseases in predisposing individuals to the development of pneumococcal infection, however, has been demonstrated primarily in adults. Mortality rates are highest in those who have bacteremia or meningitis, elderly persons, and patients with impaired humoral immunity or certain chronic diseases.

The purified polysaccharide vaccine has been effective in reducing severe disease in the adult population,[90] but it has had little impact in young children because the vaccine is not immunogenic in children younger than 2 years old.[25] In addition, the polysaccharide vaccine has not been effective in preventing otitis media caused by *S. pneumoniae*.[25]

Several factors have made the development of new preventive strategies for pneumococcal disease a high priority.[210] Morbidity and mortality rates of pneumococcal infection appear to be particularly high in developing countries. The increasing incidence of antimicrobial-resistant pneumococci further underscores the need for developing effective pneumococcal vaccines for young children.[84] Resistance of *S. pneumoniae* to multiple antibiotics has increased rapidly in the United States and even more rapidly in other parts of the world.[337] Children younger than 2 years of age have the highest rate of IPD but do not develop an effective antibody response to polysaccharide vaccine. In addition, children 2 to 5 years of age may have relatively poor responses to serotypes 6B, 14, 19F, and 23F, which are common causes of pediatric infections and the most prevalent penicillin-resistant serotypes.

These factors prompted the development of conjugated polysaccharide–protein vaccines, two of which have been licensed in the United States. These vaccines are similar in design to the licensed Hib conjugate vaccines. Because of the large number of serotypes of *S. pneumoniae* that cause disease, development of these conjugate pneumococcal vaccines has been more difficult than has the development of similar vaccines for *H. influenzae* type b. Each pneumococcal antigen must be coupled to a protein carrier, and the vaccine must be prepared to ensure that antigen is sufficient to induce an immune response but insufficient to elicit an adverse reaction.

One potential problem with conjugate pneumococcal vaccines is the need to immunize against many different serotypes of pneumococci. Because of local reactions to the protein component, conjugate vaccines that contain all implicated serotypes have proven difficult to produce. Initial decisions for serotype inclusion need to be carefully planned for specific groups. For instance, vaccine containing types 4, 6B, 9V, 14, 18C, 19F, and 23F (PCV7) would be necessary for prevention of otitis media in the United States whereas types 1, 2, and 5 would need to be added to prevent pneumonia in developing countries. Compounding this, the use of conjugate vaccines against limited serotypes has led to emergence of pneumococcal serotypes that were previously less common but have proven equally concerning for IPD and emerging resistance (e.g., 19A).[92,128,327] Specifically, emergence of replacement serotypes led to the expansion of the previous vaccine to the 13-valent pneumococcal conjugate vaccine (PCV13) in the United States. Routine infant immunization using these conjugate vaccines has led to significant reductions in the instances of *S. pneumoniae* disease. Since the widespread introduction of PCV7 in infants in 2000, rates of IPD have decreased markedly in the United States. The incidence of all IPD has decreased by 80 percent for children younger than 2 years of age and by up to 90 percent for infections caused by vaccine and vaccine-related serotypes.[25,128,572] An increase in nonvaccine serotype disease has occurred, but it is small compared with the overall reductions in vaccine-type disease.[50,92,116,128] A decline in the incidence of vaccine-type disease in unvaccinated children and adults has

occurred since the introduction of routine vaccination for infants in the United States.[116] In addition, rates of IPD in infants younger than 2 months of age have decreased significantly, thus providing evidence that vaccinating children aged 2 to 23 months has led to changes in pneumococcal carriage in infants too young to receive PCV7.[468] Herd immunity is estimated to prevent twice as many cases as do the direct effects of vaccination alone, and a similar benefit is anticipated with new serotypes included in PCV13.[116,128] Although the exact mechanism of herd immunity is uncertain, one hypothesis is that vaccinated children are less likely to have nasal carriage of pneumococcus and hence less pneumococcal transmission to their contacts.[218] Use of conjugate vaccines has been demonstrated to reduce nasopharyngeal carriage of vaccine serotypes with both PCV7 and PCV13.[204,220,221] Pneumococcal conjugate vaccination also has led to increased nasopharyngeal colonization of children with nonvaccine serotypes.[268,414] This underscores the need for ongoing surveillance of emerging nonvaccine serotypes with respect to nasopharyngeal colonization, antibiotic nonsusceptibility, as well as rates of IPD.[511]

Preparations

Two pneumococcal vaccines are available for use in children in the United States. The first is a 13-valent vaccine (PCV13) licensed in 2010 (Prevnar, Wyeth Vaccines), containing the capsular polysaccharides from serotypes contained in the previous PCV7 (4, 6B, 9V, 14, 18C, 19F, and 23F) and six additional serotypes (1, 3, 5, 6A, 7F, and 19A) conjugated to mutant diphtheria toxin (CRM_{197}).[25] Serotypes included in PCV7 and potentially cross-reactive serotypes (i.e., 6A, 9A, 9L, 18B, and 18F) accounted for 86 percent of cases of bacteremia, 83 percent of cases of meningitis, and 65 percent of AOM cases occurring in children younger than 6 years in the United States during the period 1978 to 1994.[440] In 2007, the Active Bacterial Core surveillance estimated 4600 cases of IPD in children younger than age 5 in the United States, with 2900 attributable to serotypes that would be covered by PCV13 versus 60 cases covered by PCV7.[128] The second vaccine (PPV23 [Pneumovax]) is composed of purified, capsular polysaccharide antigens of 23 pneumococcal serotypes. Although 90 different serotypes have been identified, vaccine serotypes in the 23-valent vaccine are responsible for 85 to 90 percent of adult infections and nearly 100 percent of invasive disease and 85 percent of otitis media cases in children.[98,269] Each vaccine is recommended in a dose of 0.5 mL to be given intramuscularly.

Immunogenicity and Efficacy

The immunogenicity of the conjugate polysaccharide vaccine appears to be determined by the pneumococcal polysaccharide serotype, rather than by the carrier protein. Some serotypes (14, 18C, and 19F) are excellent immunogens in that they elicit antibody protection after a single dose, whereas others (6B and 23F) require three doses of vaccine.[249] Conjugate vaccine elicits immunologic memory.[249] The antibody concentrations achieved after the initial series of three doses usually are sustained for only a few months and then decline to nearly preimmunization levels. A dose of pneumococcal vaccine, either polysaccharide or conjugate, given in the second year of life elicits an amnestic-type response.

Pre-licensure clinical efficacy of PCV7 was studied in a large, prospective, placebo-controlled efficacy trial in northern California involving 38,000 children. The vaccine was 89 percent effective in preventing invasive disease caused by any pneumococcal serotype and 97 percent effective against disease caused by the seven vaccine serotypes.[79] For noninvasive disease, a decrease of 7 percent in the number of cases of otitis media and 23 percent in doctor visits for recurrent otitis (six or more visits per year) occurred in vaccinated children. The study also demonstrated an 11 percent decrease in the number of clinical cases of pneumonia and efficacy of 26 percent against a first episode of radiograph-confirmed pneumonia in vaccines.[298,504] Pre-licensure immunogenicity of PCV13 was studied in a randomized, double-blind, active-controlled trial in which 663 U.S. infants received at least one dose of PCV7 or PCV13. The study was powered for noninferiority of immunoglobulin antibody response measured by enzyme immunoassay and also included subset analysis of functional antibody responses measured by opsonophagocytosis assay (OPA).[45,587] The noninferiority criterion (immunoglobulin geometric mean concentrations) was met for all shared serotypes; although slightly lower in the PCV13 group the functional OPA response was similar, suggesting PCV13 has similar efficacy as PCV7 against shared serotypes. After a fourth dose of PCV13, the additional six serotypes also produced a functional OPA response in 97 to 100 percent.

The ability of PCV7 to protect children against AOM also was evaluated in an efficacy trial conducted in Finland.[250] For prevention of AOM caused by pneumococci of any serotype, efficacy was estimated to be 34 percent, whereas efficacy against AOM irrespective of etiology was 6 percent. Efficacy against AOM caused by vaccine-related serotypes was 57 percent, but an increase of 33 percent in the rate of AOM episodes caused by non-vaccine serotypes occurred in the group receiving the heptavalent vaccine in comparison with controls. However, in spite of the increase in disease caused by nonvaccine serotypes, the net effect on pneumococcal AOM was a reduction of 34 percent.

Randomized controlled trials conducted in African children using a nine-valent pneumococcal conjugate vaccine demonstrated efficacy in the prevention of radiologically confirmed pneumonia and vaccine-type IPD.[215,352] The vaccine was efficacious in preventing vaccine-type invasive disease in HIV-infected children.[352] One of the trials demonstrated a reduction in all-cause mortality among vaccine recipients.[215] These data have presented a compelling case for extending the benefits of pneumococcal conjugate vaccination to developing countries.

Vaccination with purified polysaccharide vaccine results in serologic type-specific antibody in most healthy adults and older children. Immunocompromised patients may respond less well. In children younger than 2 years

old, antibody response is poor to most serotypes, including those most likely to cause infection, such as types 6A and 14.[98,147,269] Patients with AIDS have impaired antibody responses to vaccination, but asymptomatic HIV-infected adults do respond.[98,147]

Vaccine efficacy in preventing serious pneumococcal infection has been demonstrated for the purified polysaccharide vaccine primarily in immunocompetent adults, including elderly persons and those with chronic diseases such as chronic pulmonary and cardiac disorders and diabetes mellitus, which predispose these patients to development of pneumococcal infections. Efficacy against vaccine serotypes ranges from 61 to 75 percent in adults.[90,499] Investigations in adults in whom vaccine protection against pneumococcal infection has been substantially less have been criticized for methodologic problems.[98,147] Efficacy in the limited studies of children has been consistent with that in adults. In children with sickle-cell disease or anatomic asplenia, an octavalent vaccine was highly effective in preventing bacteremic infection.[49]

Adverse Events

Pneumococcal conjugate vaccines appear to be safe, and in 13 clinical trials the safety profile of PCV13 was comparable to that of PCV7.[25,45,440] The reactions most commonly reported have been local reactions at the injection site, but they occur at a lower frequency than do local reactions with other childhood vaccines such as DTP.[79]

Local reactions at the injection site, such as erythema and pain, are reported in approximately 50 percent of recipients of the purified polysaccharide vaccine.[25] However, more severe local and systemic reactions, such as fever and myalgia, are rare events that occur in less than 1 percent of vaccine recipients. Severe systemic reactions such as anaphylaxis rarely have been reported.[575] In adults who were revaccinated within 1 to 2 years in early studies, local reactions occurred more commonly than did those after initial immunization.[98,147] However, subsequent investigations, including studies in children, indicated no increase in the incidence or severity of local or systemic reactions on revaccination after longer intervals.[354,473]

Indications

Recommendations by the AAP and the ACIP for the use of PCV13 have been issued.[45,440] The AAP and ACIP recommend universal use of PCV13 in children 59 months and younger. For children in whom no prior PCV7 or PCV13 has been administered before they reach 7 months of age, four doses of PCV13 are recommended. Routinely these should be administered at 2, 4, 6, and 12 to 15 months of age. For children younger than 24 months who have not received their recommended four doses of PCV7, a dose of PCV13 should be administered at the next scheduled vaccine; the total number of doses differs based on the child's age (see elsewhere for further information[25,45,440]). A single supplemental dose of PCV13 is recommended for all children 14 months to 59 months who have previously received all four doses of PCV7. In addition, a single dose of PCV13 is recommended for children 60 months to 18 years who are fully immunized with PCV7 and have underlying medical conditions increasing their risk for IPD (see following list). If not previously administered, these children also should receive the 23-valent polysaccharide vaccine (PPV23) to expand serotype coverage.

The AAP recommends PPV23 for children 24 months or older and PCV13 for all children 59 months and older who belong to one or more of the following risk groups:

- Immunocompetent children with chronic heart disease, chronic lung disease, diabetes mellitus, cerebrospinal fluid leaks, cochlear implants
- Children with functional or anatomic asplenia, including sickle cell disease or other hemoglobinopathies, congenital or acquired asplenia, or splenic dysfunction
- Children with immunocompromising conditions, including HIV infection, chronic renal failure and nephrotic syndrome, diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease, or solid organ transplantation and congenital immunodeficiency

For previously vaccinated children 18 years old or younger who are at high risk for acquiring severe pneumococcal infection, revaccination with PPV23 after 5 years is recommended.[45,440] Such children include those who have functional (e.g., sickle-cell disease) or anatomic asplenia, children and adolescents with HIV infection, and those who have a rapid antibody decline (e.g., nephrotic syndrome, renal failure, or organ transplantation).[270] Revaccination with PPV23 should be considered for high-risk older children and adults who were vaccinated 6 years or more previously, but no more than two total PPV23 doses are necessary and the interval between polysaccharide and conjugate vaccines should be at least 8 weeks.

Contraindications

No contraindications to initial vaccination exist.[45,440] The safety of pneumococcal vaccine in pregnant women has not been evaluated, but adverse consequences to the fetus have not been observed in neonates whose mothers were vaccinated inadvertently during pregnancy. Ideally, women at high risk for acquiring pneumococcal disease should be vaccinated before pregnancy. In persons who have had a severe reaction, such as anaphylaxis or a localized, severe hypersensitivity response, revaccination should be avoided.

Poliomyelitis Vaccine

The widespread implementation of poliovirus vaccine programs resulted in a dramatic reduction in the incidence of paralytic poliomyelitis throughout the world. In contrast to the pre-vaccine era, when more than 18,000 cases of paralytic disease occurred in the United States annually, the last known case in this country caused by indigenous wild-type virus occurred in 1979.[171] Other than rare imported cases, the only cases of paralytic

poliomyelitis in the United States since then have been vaccine related. The effectiveness of polio vaccination led the WHO to launch the Global Polio Eradication Initiative in 1988, when approximately 350,000 persons succumbed to polio each year. The initiative initially made rapid gains; the number of new wild poliovirus cases decreased by 99 percent between 1988 and 2005. The last case of paralytic poliomyelitis caused by serotype 2 wild poliovirus was detected in 1999. Currently, all nations in the Western Hemisphere, the Pacific region (including China), and Europe are free of poliomyelitis.[109,150,475] However, incidence rates have plateaued since 2001, with 1,000 to 2,000 new cases annually because of regional conflicts, natural disasters, and poor health care infrastructure. All the recently reported importation-associated outbreaks of polio in eight previously polio-free countries originated from the largest remaining reservoirs of indigenous virus in Nigeria, Pakistan, Afghanistan, and India. Three countries with imported virus (Angola, Chad, and the Democratic Republic of Congo) have reestablished transmission. By 2009, sustained investments in innovative technologies and community outreach resulted in a new effective bivalent oral poliovirus vaccine (OPV)[522] and targeted supplemental immunization campaigns. Since that time, new polio cases have decreased by 95 percent in northern Nigeria, India has been declared polio free as of February 2012, and many countries where poliovirus had been reintroduced have again become polio free.[60] The hope is, that with fortified efforts, the "end game" for complete global eradication of wild-type polio is within reach.[60,151]

The elimination of poliovirus infection has been achieved primarily through the use of OPV (Sabin strain). This product had been the vaccine of choice for children in the United States since the early 1960s because it induced optimal intestinal immunity, was painless to administer, and secondarily immunized some contacts by fecal-oral spread of the vaccine virus and thus contributed to the immunity of the population.[99] Because 8 to 10 cases of vaccine-associated paralytic polio occurred annually and the risk for exposure to wild-type poliovirus had been markedly reduced or eliminated in the United States, expanded use of inactivated poliovirus vaccine (IPV, Salk strain) was recommended by the CDC and the AAP beginning in 1997.[37] In 1999, as a result of progress in the global eradication of poliomyelitis, the need for further reduction in the risk for acquiring vaccine-associated paralytic polio, and the acceptance of IPV by parents and physicians,[126] IPV was recommended for the first two doses of poliovirus vaccine for routine childhood vaccination.[38,156] To eliminate the risk for vaccine-associated paralytic polio completely, in January of 2000 an all-IPV schedule was recommended for routine childhood vaccination in the United States.[40,156,158]

Since 2000, outbreaks of paralytic poliomyelitis caused by neurovirulent polioviruses that are derived from Sabin OPV vaccine strain have occurred among underimmunized children living in certain economically deprived regions. The low immunization rates in these areas have permitted these viruses, called vaccine-derived polioviruses (VDPVs), to circulate for long periods of time and, by continuous mutation, to acquire biologic properties that are indistinguishable from naturally occurring wild polioviruses. Outbreaks associated with circulating VDPVs have occurred in Hispaniola (2000 through 2001), the Philippines (2001), and Madagascar (2001 through 2002).[105,140,345,580] Retrospective studies also detected the circulation of endemic VDPV in Egypt (1988 through 1993) and the likely localized spread of OPV-derived virus in Belarus (1965 through 1966).[112,346] Gaps in OPV coverage and the previous eradication of the corresponding serotype of indigenous wild poliovirus were the critical risk factors for all VDPV outbreaks.[346] The VDPV outbreaks were stopped by mass immunization campaigns using OPV. The potential risk for emergence of VDPV has increased dramatically in recent years as wild poliovirus circulation has ceased in most of the world. The risk appears to be highest for the type 2 OPV strain, which was found in eight of nine countries with VDPV outbreaks between 2008 and 2010, because of its greater tendency to spread to contacts.[169,170] The emergence of VDPVs underscores the critical importance of eliminating the last pockets of wild poliovirus circulation, maintaining universally high levels of polio vaccine coverage (>90% of young children), stopping OPV use as soon as it is safely possible to do so, and continuing sensitive poliovirus surveillance into the foreseeable future. Particular attention must be given to areas where the risks for wild poliovirus circulation have been highest and where the highest rates of polio vaccine coverage must be maintained to suppress VDPV emergence.

Preparations

Trivalent IPV is the only vaccine available for routine infant and childhood immunization in the United States. IPV is prepared by inactivation of naturally occurring polioviruses by treatment with dilute formalin.[156] Four trivalent IPV vaccines are now available in the United States: IPOL (Aventis Pasteur), Pediarix (in combination with DTaP vaccine and HBV vaccine, GlaxoSmithKline), Pentacel (in combination with DTaP vaccine and Hib vaccine, Sanofi Pasteur), and Kinrix (in combination with DTaP vaccine, GSK). These vaccines are produced in monkey kidney (Vero) cells, and each contains 40-, 8-, and 32-D-antigen units of poliovirus types 1, 2, and 3, respectively. OPV is no longer available in the United States.

The trivalent OPV formulations available globally contain approximately $10^{6.5}$ 50 percent tissue culture infectious doses ($TCID_{50}$), $10^{5.5}$ $TCID_{50}$, and $10^{6.2}$ $TCID_{50}$ of poliovirus types 1, 2, and 3, respectively. The unequal contribution of each type to the trivalent preparation represents a "balanced" formulation designed to account for the more efficient replication of type 2 OPV virus in the gastrointestinal tract; if type 2 were given in equal concentrations with types 1 and 3, it would interfere with the replication of the two latter types. The live oral OPV strains originally were attenuated by passage in monkeys and in monkey kidney cell culture.

Trivalent IPV is now the preferred vaccine for other developed countries. However, because OPV maintains certain advantages for children in developing countries,

including cost, ease of administration, and transmission of vaccine virus to unimmunized contacts, it is the vaccine currently recommended by the WHO EPI.[579] The trivalent form of OPV has been the mainstay of EPI and the WHO Polio Eradication Program for many years. A new bivalent OPV vaccine (serotypes 1 and 3) has been available since 2009 and may replace the trivalent vaccine given that poliovirus type 2 is no longer in circulation.[151,522] Monovalent OPV vaccines have been introduced for outbreak control in certain settings.

Immunogenicity and Efficacy

Neutralizing antibodies are detectable to all three poliovirus types in 99 percent of recipients of IPV after two doses and in 100 percent after the third dose.[403,509] IPV-immunized children experience a large boost in antibody titer after receiving the third dose.[475] Detectable antibody persists at protective levels for at least 5 years, although geometric mean titers decline considerably.[523] However, few data are available regarding vaccine efficacy of the currently licensed "enhanced-potency" IPV formulations. A case-control study in Senegal indicated lower than expected protection rates of 36 and 89 percent for recipients of one and two doses, respectively.[476] However, because most IPV recipients experience a substantial boost in antibody titer after receiving a third dose, efficacy after three IPV doses likely would be quite high.

An optimal immune response to trivalent OPV requires multiple doses. In developed countries, three doses given at least 2 months apart are sufficient, with antibody prevalence to all three types being approximately 96 percent after the third dose.[403] Detectable serum antibody to all three types persists in 84 to 98 percent of vaccinees 5 years after receiving primary immunization.[361]

OPV efficacy was directly evaluated during a type 1 poliovirus outbreak in Taiwan in the early 1980s. During this outbreak, vaccine efficacy was estimated to be 82, 96, and 98 percent for one, two, and three or more doses, respectively.[347] In tropical countries, the series of OPV at 6, 10, and 14 weeks of age recommended by the WHO EPI fails to produce active immunity in a significant proportion of infants. Low seroconversion rates have been documented in many locations, averaging 73, 90, and 70 percent for types 1, 2, and 3, respectively.[455] Diarrheal disease at the time of immunization is a major factor.[431] The impact of diarrhea on seroconversion persists despite the administration of three or four OPV doses.

The monovalent OPV vaccines have higher type-specific seroconversion rates than does the trivalent vaccine and thus may be more effective when used in response to an outbreak caused by one poliovirus type.[93]

Adverse Events

No serious adverse events have been associated with use of the currently available IPV vaccine.[26,40,156] Because IPV vaccine contains trace amounts of streptomycin, neomycin, and polymyxin B, allergic reactions are possible in recipients with hypersensitivity to one or more of these antibiotics.

The OPV vaccine can cause vaccine-associated paralytic polio, the overall risk for which is approximately one case per 2.4 million doses distributed. The rate after the first dose is approximately one case per 750,000 doses, including vaccine recipient and contact cases. Chronic VDPV excretion by persons with severe primary B-cell immune defects is a rare complication of OPV use and it may cause fatal disease.

Indications

The polio vaccination series in the United States consists of four doses of IPV administered subcutaneously or intramuscularly.[26,40,156] The first and second doses are administered at 2 and 4 months of age, respectively. The third dose is usually given at 6 to 18 months of age, and a fourth dose is given routinely at 4 to 6 years of age, before school entry. Administration of a fourth dose is not necessary if the third dose was given on or after the child's fourth birthday. IPV is a component of Pediarix, Pentacel, and Kinrix. Pentacel may be used in children from 6 months to 18 months of age, and Kinrix may be used for children 4 to 6 years of age.

The ACIP and AAP continue to support the global eradication initiative and use of OPV as the vaccine of choice to eradicate wild-type polio in endemic areas and during epidemics. In the immunization schedule of the EPI of the WHO, doses of OPV are recommended at birth and when the child is 6, 10, and 14 weeks of age.[9] In geographic areas with endemic polio, a dose may be given when the neonate is discharged from the hospital. Supplementary doses often are given during mass community programs in these areas. Breast-feeding does not interfere with successful immunization with OPV.

Routine poliovirus vaccination is not necessary in adults residing in the United States. Such individuals are at minimal risk for exposure, and most are adequately protected because of vaccination during childhood. However, vaccination is recommended for individuals who have increased risk for exposure, including persons traveling to countries where poliomyelitis is epidemic or endemic, members of communities of specific population groups experiencing wild-type poliovirus disease, health care workers in close contact with patients who may be excreting wild-type poliovirus, and laboratory workers in contact with specimens that may contain wild-type poliovirus. Previously immunized adults who are at increased risk for exposure to poliomyelitis, such as those traveling to countries where poliomyelitis is still endemic, should receive a single dose of IPV. Available data do not indicate the need for more than a single lifetime booster dose of IPV. Adults who are unvaccinated or whose vaccination status is not documented should receive a primary vaccination series with IPV. This consists of two doses of IPV at 4- to 8-week intervals and a third dose 6 to 12 months after the second dose.

Precautions and Contraindications

IPV is contraindicated in persons who have experienced an anaphylactic reaction after receiving a previous dose of IPV or an anaphylactic reaction to one of the

antibiotics in the vaccine preparation (i.e., streptomycin, polymyxin B, or neomycin).[26,40,156] Poliomyelitis vaccination generally is contraindicated in pregnant women because of the theoretical risk for harm to the fetus. However, no deleterious effects from IPV administered during pregnancy have been demonstrated; and if immediate protection against poliomyelitis is needed, IPV may be given.

Rotavirus Vaccine

Rotavirus, a major cause of childhood morbidity and mortality, causes an annual 440,000 deaths or approximately 5 percent of all childhood deaths worldwide. Rotavirus is also a major cause of acute gastroenteritis in the United States. In their first 5 years of life, 4 of 5 children in the United States will develop rotavirus gastroenteritis, 1 in 7 will require a clinic or emergency department visit, 1 in 70 will be hospitalized, and 1 in 200,000 will die of this disease.[257,272,386,534]

Rotavirus gastroenteritis is preventable with live oral rotavirus vaccines. In 1998, the only approved rotavirus vaccine, a tetravalent rhesus-based rotavirus vaccine (RRV-TV, Rotashield, Wyeth Laboratories), was withdrawn from the market in the United States because of an association with intussusception among vaccinated infants.[430] In 2006, a bovine-based pentavalent rotavirus vaccine (RotaTeq, Merck & Co.) was licensed by the FDA for use in infants in the United States. Both the ACIP of the CDC and the AAP have recommended universal vaccination of U.S. infants against rotavirus.[41,212] In 2008 a live attenuated human rotavirus vaccine (Rotarix, GlaxoSmithKline) was licensed in the United States.

The epidemiology of rotavirus disease in the United States has changed dramatically since rotavirus vaccines became available in 2006. The rotavirus season now is shorter and relatively delayed, peaking in late spring, and the overall burden of rotavirus disease has declined dramatically.[115] In the first 2 years after the RV5 vaccine became available, emergency department visits and hospitalizations for rotavirus decreased by 85 percent, such that in the 2008 season there were an estimated 40,000 to 60,000 fewer gastroenteritis hospitalizations among children younger than 5 years of age compared with prevaccine seasons.[160] There also were substantial reductions in office visits for gastroenteritis during this time period.

Preparations

There are currently two rotavirus vaccines licensed for use in the United States. The pentavalent rotavirus vaccine (RV5) is an oral vaccine that contains five live reassortant rotaviruses. The rotavirus parent strains of the reassortants were isolated from human and bovine hosts. Four reassortant rotaviruses express one of the outer capsid proteins (G1, G2, G3, or G4) from the human rotavirus parent strain and the attachment protein (P7[5]) from the bovine rotavirus parent strain. The fifth reassortant virus expresses the attachment protein (P1A[8]) from the human rotavirus parent strain and the outer capsid protein G6 from the bovine rotavirus parent strain. The reassortants are propagated in Vero cells using standard tissue culture techniques.

RV5 vaccine is provided in a squeezable plastic dosing tube with a twist-off cap designed to allow for the vaccine to be administered directly to infants by mouth. Each tube contains a single 2-mL dose of the vaccine as a liquid buffered-stabilized solution.

The human rotavirus vaccine (RV1) is a G1 P1A[8] virus attenuated by passage in cell culture. RV1 is provided as a lyophilized powder that is reconstituted with a supplied diluent before administration.

Both rotavirus vaccines must be stored at refrigerator temperatures (2° C to 8° C [35° F to 46° F]) and protected from light. RV1 diluent may be stored at room temperature. The vaccines must not be frozen. The shelf life of properly stored vaccine is 24 months. RV5 should be administered as soon as possible after being removed from refrigeration. RV1 should be administered within 24 hours of reconstitution. Reconstituted RV1 may be stored at refrigerator or room temperature.

No studies have addressed the interchangeability of the rotavirus vaccines.

Immunogenicity and Efficacy

The immune correlates of protection from rotavirus infection and disease are not fully understood. In a large phase III clinical trial of RV5, an increase in titer of rotavirus group-specific serum IgA antibodies was used as one of the measures of the immunogenicity. Serum samples were obtained from a subset of study participants before they were immunized and approximately 2 weeks after they received the third dose; seroconversion was defined as a threefold or greater increase in antibody titer from baseline. Seroconversion rates for IgA antibody to rotavirus were 95 percent among vaccine recipients versus 14 percent in recipients of the placebo.[548]

The efficacy of RV5 was evaluated in two phase III trials.[81,548] In these trials, the efficacy of RV5 after completion of a three-dose regimen against rotavirus gastroenteritis of any severity was 74 percent and against severe rotavirus gastroenteritis it was 98 percent. Efficacy was observed against all G1 to G4 and G9 serotypes, but relatively few non-G1 rotavirus cases were reported. RV5 reduced the incidence of office visits by 86 percent, emergency department visits by 94 percent, and hospitalizations for rotavirus gastroenteritis by 96 percent. The efficacy of RV5 in the second rotavirus season after immunization was 63 percent against rotavirus gastroenteritis of any severity and 88 percent against severe rotavirus gastroenteritis. Neither breast-feeding nor concurrent administration of other childhood vaccines appears to diminish the efficacy of a three-dose series of RV5. The efficacy of fewer than three doses is not known.

Phase III clinical trials of RV1 efficacy have involved more than 21,000 infants 6 through 12 weeks of age, primarily in two studies in Latin America and Europe.[486,546] After completion of a two-dose RV1 regimen, the efficacy of rotavirus vaccine against severe rotavirus gastroenteritis (Latin America study) was 85 percent, and against any rotavirus gastroenteritis (Europe study) it was 87 percent.

RV1 reduced hospitalization for rotavirus gastroenteritis by 85 to 100 percent (depending on the study). The efficacy of fewer than two doses is not known.

Adverse Events

Safety with respect to intussusception was evaluated in 71,725 subjects enrolled in phase III efficacy trials of RV5.[81,548] For the prespecified 42-day postimmunization end point, six cases of intussusception were observed in the RV5 group versus five cases of intussusception in the placebo group (multiplicity-adjusted relative risk, 1.6). The data did not suggest an increased risk for development of intussusception relative to placebo. Among vaccine recipients, no confirmed cases of intussusception occurred within the 42-day period after administration of the first dose, which was the period of highest risk for the previously licensed RRV-TV vaccine. In addition, no evidence of clustering of cases of intussusception was observed within a 7- or 14-day window after immunization for any dose. For the 1-year follow-up period after administration of the first dose, 13 cases of intussusception were observed in the RV5 group versus 15 cases of intussusception in the placebo group (multiplicity-adjusted relative risk, 0.9).

Some studies performed outside the United States have detected a low level of increased risk for intussusception after rotavirus immunization shortly after the first dose. The level of risk observed in these postmarketing studies is substantially lower than the risk for intussusception after immunization with RotaShield, the previous rotavirus vaccine.[91,453,542] Although an increased risk for intussusception from rotavirus vaccine has not been documented in the United States, data currently available cannot exclude a risk as low as that detected in other locations.

Both vaccines are well tolerated and have a low reactogenicity profile when given alone. They do not cause clinically significant increases in reactogenicity when coadministered with other routine childhood vaccines.[229,480] For both vaccines, the incidence of fever, vomiting, diarrhea, and irritability were measured in the clinical trials. For RV5, no significant difference versus placebo was observed in the incidence of fever or severe fever and irritability or severe irritability. A 3 percent increase in the incidence of diarrhea and vomiting was observed with RV5, but these symptoms were mild and did not require treatment.[81,231,548] For RV1, no difference versus placebo was observed in the incidence of diarrhea, fever or severe fever, vomiting or severe vomiting, and irritability or severe irritability within 14 days of immunization with any dose.[230,461,545,547] There was no statistically significant increased risk for death or other serious adverse events noted with either vaccine compared with placebo.

Vaccine virus shedding in stool has been documented with both rotavirus vaccines. Rotavirus shedding occurs in approximately 9 percent of RV5 recipients after the first dose but rarely after subsequent doses.[231] No cases of transmission of RV5 have been documented. Shedding and transmission are not considered significant safety concerns because of the attenuated nature of the rotavirus vaccine strains. For RV1, live rotavirus shedding in stool occurs in approximately 25 percent of recipients, with peak excretion occurring around day 7 after the first dose. Transmission of virus has not been evaluated. There have been a few cases of documented transmission to contacts. The rate of transmission is unknown, but there are no known cases of patients who have developed symptoms of rotavirus gastroenteritis.[461]

In 2010, porcine circovirus or porcine circovirus DNA was detected in both rotavirus vaccines.[271,363,404] There is no evidence that this virus is a safety risk or causes illness in humans.

Indications

Infants should receive three doses of RV5 administered orally at 2, 4, and 6 months of age or two doses of the RV1 at 2 and 4 months of age.[41,212] The first dose should be administered when the child is between 6 and 14 weeks of age (i.e., on or before 14 weeks, 0 days of age). Subsequent doses should be administered at a minimum of 4-week intervals, and all doses of vaccine should be administered by the time the child is 32 weeks of age (i.e., on or before 32 weeks, 0 days).

Immunization should not be initiated for infants older than 14 weeks because of insufficient data on safety of the first dose of rotavirus vaccine in older infants. Vaccine should not be administered after 8 months of age because of insufficient data on the safety and efficacy of rotavirus vaccine in infants after this age. For infants in whom the first dose of rotavirus vaccine is inadvertently administered off-label at 15 weeks or older, the rest of the rotavirus immunization series should be completed as per the schedule defined earlier, because timing of the first dose should not affect the safety and efficacy of the second and third doses.

The rotavirus vaccine series should be completed with the same product whenever possible. However, vaccination should not be deferred if the product used for a prior dose or doses is not available or is not known. In this situation, the provider should continue or complete the series with the product that is available. If any dose in the series was RV5 (RotaTeq) or the vaccine brand used for any prior dose in the series is not known, a total of three doses of rotavirus vaccine should be administered.

Infants documented to have had rotavirus gastroenteritis before receiving the full course of rotavirus immunizations should still start or complete the three-dose schedule because the initial infection frequently provides only partial immunity.

Infants who are being breast-fed can receive rotavirus vaccine. Like other childhood vaccines, rotavirus vaccine can be administered to infants with transient, mild illnesses, with or without low-grade fever.[358] Rotavirus vaccine can be administered together with DTaP, Hib, IPV, hepatitis B, and pneumococcal conjugate vaccines.

The AAP and ACIP support immunization of preterm infants under the following conditions: the infant is at least 6 weeks of age, the infant is clinically stable, and the first dose of vaccine is given at the time of discharge or after the infant has been discharged from the hospital nursery.

Infants living in households with persons who have or are suspected of having an immunodeficiency disorder or impaired immune status or with a pregnant woman can be immunized. To minimize potential virus transmission, all members of the household should employ measures such as good hand washing after contact with the feces of the immunized infant (e.g., after changing a diaper) for at least 1 week after the first dose of rotavirus vaccine has been given.

An infant who regurgitates, spits out, or vomits during or after receiving a dose of rotavirus vaccine should not have that dose readministered. The infant can receive the remaining recommended doses of rotavirus vaccine at appropriate intervals. If a recently immunized child is hospitalized for any reason, no precautions other than standard precautions need be taken to prevent the spread of vaccine virus in the hospital setting.

Contraindications and Precautions

Rotavirus vaccine should not be administered to infants who have severe hypersensitivity to any component of the vaccine or those individuals who have experienced a serious allergic reaction to a previous dose of rotavirus vaccine.[41,212] The RV1 oral applicator contains latex rubber. RV5 may be preferred for children at high risk for acquiring latex sensitization.

Practitioners should consider the potential risks and benefits of administering rotavirus vaccine to infants with known or suspected altered immunocompetence. Children and adults who are immunocompromised because of congenital immunodeficiency, bone marrow transplantation, or solid organ transplantation sometimes experience severe, prolonged, and even fatal rotavirus gastroenteritis. However, no safety or efficacy data are available for the administration of rotavirus vaccine to infants who are potentially immunocompromised with the exception of infants with severe combined immune deficiency (SCID). SCID is a contraindication for use of both rotavirus vaccines.[106] Gastroenteritis, including severe diarrhea and prolonged shedding of vaccine virus, have been reported in infants who were administered live, oral rotavirus vaccines and later identified as having SCID.[61]

Rotavirus vaccine should not be administered to infants with acute, moderate to severe gastroenteritis until the condition improves. Rotavirus vaccine has not been studied among infants with concurrent acute gastroenteritis, among whom its immunogenicity and efficacy theoretically can be compromised. Infants with moderate to severe illness should be immunized as soon as they have recovered from the acute phase of the illness.

Infants with preexisting chronic gastrointestinal conditions and who are not undergoing immunosuppressive therapy should benefit from rotavirus vaccine immunization, and the benefits outweigh the theoretical risks. However, the safety and efficacy of rotavirus vaccine have not been established for infants with these preexisting conditions (e.g., congenital malabsorption syndromes, Hirschsprung disease, short-gut syndrome, or persistent vomiting of unknown cause).

A history of intussusception is a contraindication for use of both rotavirus vaccines. Some data suggest that infants with a history of intussusception may be at higher risk for having a repeat episode than are other infants.

Rubella Vaccine

Rubella is a viral disease that usually is manifested as a mild febrile rash illness in adults and children; however, 20 to 50 percent of infected persons are asymptomatic. Rubella can have severe adverse effects on the fetuses of pregnant women who contract the disease during the first trimester of pregnancy; it causes a wide range of congenital defects known as congenital rubella syndrome. The primary objective of the rubella vaccination program is to prevent intrauterine rubella infection. The primary strategies for rubella control in the United States are universal childhood vaccination, prenatal screening of pregnant women for rubella immunity, and vaccination of rubella-susceptible women postpartum.

In the pre-vaccine era, epidemics of rubella occurred every 6 to 9 years, with the last major epidemic in the United States taking place in 1964 through 1965. The incidence of reported cases of rubella fell sharply after routine rubella immunization of young children was initiated in the United States in 1969. From the estimated 2 million cases per year in the pre-vaccine era, fewer than 1000 cases were reported in 1983. A moderate resurgence of rubella occurred in 1990 through 1991, primarily due to outbreaks in California (1990) and among the Amish in Pennsylvania (1991). Since the mid 1990s, most reported cases of rubella have occurred among foreign-born young adults (particularly from Latin America) who were born in countries without routine rubella immunization programs.[222,469] In 2003, a record low annual total of seven cases was reported.

In October 2004, 35 years after initiation of the rubella immunization program, an independent panel of international experts was convened by the CDC to assess progress toward elimination of rubella and congenital rubella syndrome. Based on data showing fewer than 25 cases of rubella reported each year since 2001, at least 95 percent vaccination coverage among school-aged children, an estimated 91 percent population immunity, adequate surveillance to detect rubella outbreaks, and a pattern of virus genotypes consistent with virus originating in other parts of the world, panel members concluded unanimously that rubella no longer is endemic in the United States.[117]

Rubella continues to be endemic in many parts of the world. Internationally imported rubella cases may give rise to indigenous transmission. The United States will need to continue its vigilance against rubella and congenital rubella syndrome by the following means: (1) maintaining high vaccination rates among children; (2) ensuring vaccination among women of child-bearing age, especially women born outside the United States; (3) continuing surveillance of both rubella and congenital rubella syndrome; and (4) responding rapidly to any outbreak.[117]

Preparations

Since 1979, RA 27/3 (rubella abortus, 27th specimen/third extract) vaccine, prepared in human diploid tissue culture, has been the only vaccine available in the United States; it replaced the earlier HPV-77 and Cendehill vaccines. RA 27/3 induces higher antibody titers and more closely parallels the immune response after natural infection than did previous vaccines.[371,446] Two rubella-containing vaccines, MMR and MMRV, are available. Both vaccines should be kept at 2°C to 8°C (35.6°F to 46.4°F) or colder during storage and should be protected from light to avoid inactivation of the virus. Once reconstituted, the vaccine should be used within 8 hours.

Immunogenicity and Efficacy

At least 98 percent of susceptible vaccinees aged 12 months or older develop antibody titers that are protective.[417] Vaccine-induced rubella antibodies have persisted in more than 90 percent of vaccinees aged 16 years old after receiving the RA 27/3 vaccine.[194] Lifelong protection against clinical reinfection, asymptomatic viremia, or both, usually results from a single dose of vaccine given early in childhood.

In some cases, vaccinees exposed to natural rubella developed a rise in antibody titer unassociated with clinical symptoms. Reinfection is associated only rarely with viremia. Significant pharyngeal shedding also is observed infrequently. Person-to-person transmission, however, has not been reported. Reinfection caused by wild-type rubella virus also may be observed in individuals with previous natural rubella. The risk for CRS developing from rubella reinfection during pregnancy is extremely low.[477]

Adverse Events

Rubella vaccines generally are well tolerated. The most frequent complaints after vaccination are fever, lymphadenopathy, or rash, which occur in 5 to 15 percent of children 5 to 12 days after receiving vaccination.[27] Transient peripheral neuritis (paresthesia and pain in the arms and legs) has been observed uncommonly, primarily in older age groups.[492]

Approximately 3 percent of children have transient joint manifestations, including arthralgia and, less commonly, arthritis 1 to 3 weeks after being immunized. Although 25 percent of women report having joint pain after being vaccinated, arthritis with objective clinical findings lasting less than 10 days occurs in 13 to 15 percent. Cases of persistent or recurrent joint symptoms have been reported but are rare events. In 1992, the IOM reviewed the existing data on rubella and adverse joint events and concluded that the evidence available was consistent with a causal relationship between rubella vaccination and chronic arthritis in women, although data on current vaccine strains are limited.[314] The incidence of joint manifestations after immunization is lower than that after natural infection at the corresponding age.

Rubella revaccination is well tolerated, even among college-aged and older vaccinees, and is associated with a much lower incidence of adverse reactions than is primary rubella immunization of young adult populations. Reported rates of joint-related complaints of 4 to 18 percent after revaccination are lower than those reported after primary vaccination.[190,496]

Indications

Live virus rubella vaccine generally is recommended for all children aged 12 months or older; it is given as MMR or MMRV when children are 12 to 15 months of age.[27,114,133] A second dose of rubella vaccine administered as MMR or MMRV is given at the time they enter school, usually 4 to 6 years of age, according to recommendations for routine measles immunization. The vaccine should be provided to previously unimmunized preschool-aged children or older schoolchildren despite a history of having clinical rubella, unless serologic tests confirm immunity.

Emphasis should be placed on the immunization of the postpubertal male and female population, especially college students and those in the military. Rubella vaccine also should be administered to adolescent girls and women of child-bearing age who lack a history of previous vaccination. Other opportunities for immunization include premarital screening, routine gynecologic examinations, visits for neonatal and well-child care, or other medical visits. The immediate postpartum period also is an excellent time for giving immunizations. Rubella vaccine may be given after administration of anti-Rho(D) immune globulin, but serologic testing to determine whether seroconversion has occurred should be performed at least 8 weeks after vaccination. When practical, potential vaccinees may be screened for susceptibility. However, vaccination of girls and women of child-bearing age is justifiable and may be preferable, without previous serologic testing in women not known to be pregnant.

Adults in the United States who were born in countries where rubella vaccination was not offered are at higher risk for contracting rubella and having infants with CRS. Health care practitioners who treat foreign-born adults should document the rubella immunity of these patients with a written record of rubella-containing vaccine or by serologic testing. Susceptible adults, especially women of child-bearing age, should be vaccinated. During rubella outbreaks, all susceptible persons who have no contraindications to rubella vaccine should be identified and vaccinated.

Precautions and Contraindications

Specific contraindications to administration of live rubella vaccine include the following: (1) pregnancy; (2) severe febrile illness; (3) known history of anaphylactic reaction to rubella vaccine, gelatin, or neomycin, which are contained in the vaccine; and (4) immunodeficiency conditions (i.e., malignancy, primary immunodeficiency disease, immunosuppressive or corticosteroid therapy, and radiation therapy).[27,114,133]

Persons with mild immunosuppression, such as those with asymptomatic HIV infection or those taking short-term or low-dose corticosteroids, may be vaccinated.

Postpubertal women of child-bearing age who are known to be pregnant or who are attempting to become pregnant should not be vaccinated. Vaccinated women should be counseled about the need to avoid pregnancy for 28 days after receiving vaccination.[162] Although pregnancy is a contraindication to administering rubella vaccination, the maximal theoretical risk to the fetus is estimated to be 1.6 percent. From 1979 until 1989, the CDC registered 321 susceptible women who inadvertently had received RA 27/3 rubella vaccine within 3 months before or after conception and carried their pregnancies to term. None of their infants had defects compatible with CRS, although 2 percent had serologic evidence of intrauterine infection.[101] Because rubella virus has been isolated from the products of conception of women vaccinated during pregnancy, continued caution with respect to vaccination during pregnancy is advised. However, the evidence available indicates that rubella vaccination inadvertently given during pregnancy ordinarily does not represent a reason to consider interruption of pregnancy.

Although vaccine virus may be isolated from the pharynx, vaccinees do not transmit rubella to others, except in the case of a vaccinated breast-feeding mother. In this situation, the infant may be infected through breast milk and a mild rash illness may develop, but serious adverse effects have not been noted. Infants infected through breast-feeding respond normally to rubella vaccination at 15 months of age. Breast-feeding is not a contraindication to receiving rubella vaccination.

Concern about potential transmission of disease from immunized children to susceptible contacts, including pregnant women, has not been supported by studies of susceptible household contacts. Therefore, susceptible children whose household contacts are pregnant may be vaccinated.

Persons with a history of thrombocytopenia may experience thrombocytopenia after receipt of MMR vaccine. The decision to vaccinate should depend on the benefits of immunity versus the risk for recurrence or exacerbation of thrombocytopenia, either after vaccination or during natural infection with measles or rubella.

Rubella vaccine should not be given during an interval beginning 2 weeks before and extending 3 months after the administration of immune globulin or blood transfusion. Because rubella vaccine usually is given as MMR or MMRV, and evidence suggests that high doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage, rubella vaccination with MMR or MMRV necessitates deferral for longer periods (see Measles Vaccine).[27,133,506]

Tetanus Toxoid

The efficacy of active immunization against tetanus was demonstrated most dramatically in military personnel during World War II, when tetanus toxoid virtually eliminated tetanus in injured servicemen. Since the 1940s, routine immunization of civilians in this country with tetanus toxoid has been successful in nearly eliminating tetanus. In almost all cases, disease has been reported in unimmunized or inadequately immunized individuals.[104] The primary three-dose series of a tetanus toxoid-containing vaccine confers protective immunity for 10 years or longer.[86,357]

Without a tetanus booster, immunity wanes over time. The potential for occurrence of tetanus is indicated by the significant number of adults in the United States who lack protective concentrations of serum antibody.[264] Although the incidence of disease is exceptionally low (a total of 624 cases of tetanus were reported in the United States between 1990 and 2004), the case-fatality rate was 18 percent.[452,513]

Neonatal tetanus also has been nearly eliminated in the United States. However, it is a leading cause of morbidity in neonates in developing countries. As a result, global elimination of neonatal tetanus remains a goal of the WHO.[152]

Preparations

Tetanus toxoid is prepared by formaldehyde treatment of *Clostridium tetani* toxin.[86,357] It has been prepared in both fluid and aluminum salt-adsorbed preparations, but in the United States only the latter is available. Fluid toxoid preparations result in a significantly shorter duration of immunity than that induced by aluminum-adsorbed antigens; therefore, adsorbed antigens are recommended.

Tetanus toxoid is available in combination with diphtheria toxoid and acellular pertussis vaccine (DTaP) for routine administration to infants and children younger than 7 years of age and for adolescents and adults aged 11 years and older as a single booster (Tdap). For all persons in whom pertussis vaccine is contraindicated, tetanus toxoid is combined with diphtheria toxoid as either DT or Td (see Diphtheria Toxoid). The first two Tdap vaccines approved for use in adolescents and adults in the United States, Boostrix (GlaxoSmithKline Biologicals) and Adacel (Sanofi Pasteur), were licensed in 2005. Preparations of DT, Td, and Tdap are identical in the amounts of tetanus toxoid they contain, but they differ in the quantity of diphtheria toxoid. The dose of Tdap is the same as that of DT or Td, 0.5 mL administered intramuscularly.

Immunogenicity and Efficacy

Adequate primary immunization provides sufficient protective titers of antitoxin for at least 10 years and ensures prompt, anamnestic responses to subsequent booster injections. Immune response to tetanus toxoid was measured after administration of each adult Tdap vaccine and compared with that elaborated after Td vaccine. Seroprotective anti-tetanus antibody concentrations, defined as a titer 0.1 IU/mL or greater, and booster response rates to tetanus were determined to be noninferior after vaccination with Tdap as compared with Td vaccination.[86,357]

Adverse Events

Local reactions of pain, swelling, and induration can occur, but these reactions in children usually are attributable to the pertussis component contained in the vaccine rather than to response to tetanus toxoid.[29] Hypersensitivity reactions can occur in adolescents and adults but very rarely are severe. Neurologic reactions occurring after the administration of tetanus toxoid are rare events. Such reactions include brachial neuritis and Guillain-Barré syndrome.

Regarding adverse reactions reported after Tdap, vaccination with Boostrix was associated with a statistically higher rate of moderate to severe headache compared with Td and that with Adacel was associated with higher rates of mild injection site pain and low-grade fever compared with the Td vaccine. No serious adverse events have been reported for Boostrix. Two cases of serious adverse advents, both characterized as neuropathic reactions, in adults possibly related to having received Adacel (none reported in adolescents), have been reported, and in both cases symptoms resolved completely within several days.[86,357]

Indications

Preexposure. For primary immunization, doses of tetanus toxoid, provided as DTaP, should be administered when the child is 2, 4, and 6 months of age.[29,39,86] A fourth dose is given 6 to 12 months after the third dose (i.e., at 12 to 18 months of age) to maintain adequate serum antibody concentrations for the ensuing preschool years. For children younger than 7 years of age not immunized in infancy, DTaP is given at birth (initial dose), 2, 4, and 10 to 16 months later, followed by a single booster dose at age 4 to 6 years, just before school entry.

In 2005, the FDA licensed two Tdap vaccines for routine use in adolescents and adults, Adacel (Sanofi Pasteur, approved for persons 11 to 64 years of age) and Boostrix (GlaxoSmithKline Biologicals, approved for adolescents 10 years of age and older). These vaccines are approved for one-time use only in those individuals who have previously completed their primary vaccination series with DTP or DTaP, as a substitute for their next Td booster.[182] The preferred age for Tdap vaccination is 11 to 12 years. Catch-up vaccination with Tdap is encouraged for adolescents 13 to 18 years old who completed their primary series with DTP or DTaP and have not received a Td or Tdap booster. Adolescents 11 through 18 years of age who received Td but not Tdap are encouraged to receive a single dose of Tdap to provide protection against pertussis if they have completed the recommended childhood DTP/DTaP immunization series. Tdap should be administered regardless of interval since the last tetanus or diphtheria toxoid-containing vaccine. Although longer intervals between Td and Tdap could decrease the occurrence of local reactions, the benefits of protection against pertussis outweigh the potential risk for adverse events.[29,182] Every 10 years thereafter, tetanus booster should be provided by Td. Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis should receive Tdap initially, followed by Td for the subsequent two doses 4 or more weeks and then 6 to 12 months later. For children between the ages of 7 and 10 years who have not been vaccinated previously, Tdap vaccine should substitute an initial dose of Td in the catch-up series, followed by two subsequent doses of Td vaccine at 4 or more weeks, and 6 to 12 months after the previous dose.[29,182] Interruption of the recommended schedule or delay in administering subsequent doses during primary immunization does not reduce immunity.

Antepartum. In areas of the world where the risk for acquiring neonatal tetanus is significant, previously unimmunized, pregnant women should receive two antepartum doses of a tetanus toxoid-containing vaccine, properly spaced at least 4 weeks apart, and the second dose should be given at least 2 weeks before delivery and should complete the three-dose series subsequently.[277,357] Tdap should be substituted for the first Td dose if Tdap has not been administered previously. Immunization with Tdap is recommended during pregnancy, preferably at 20 weeks' gestation or later, if Tdap has not been administered previously. Women immunized more than 10 years previously should receive a booster dose with Td or Tdap if Tdap has not been administered previously.[29,182] If vaccination is not provided before delivery or during pregnancy, women who have not received Tdap vaccine previously should receive a single dose of Tdap in the immediate postpartum period, preferably before being discharged from their hospital or birthing center.

Postexposure Wound Management. The potential need for immunoprophylaxis is an integral aspect of wound management at the time of trauma or injury. The recommended use of tetanus toxoid in addition to tetanus immune globulin at the time of injury is given in Table 244-14. To ensure adequate immunity, children and adults receiving tetanus toxoid for wound management should be given age-appropriate preparations of vaccines containing diphtheria and pertussis, unless contraindicated, as well as tetanus toxoid. Tdap is preferred over Td if the person has not received Tdap previously.[29,182] Specific recommendations depend on the individual's immunization status, the nature of the wound, and the duration of time between when the injury occurred and evaluation and treatment were undertaken. After prophylaxis is provided, primary immunization should be completed subsequently in those lacking the recommended number of doses. This conservative approach to the frequent administration of booster doses of tetanus toxoid in wound management for previously immunized persons is supported by the prolonged immunity from tetanus vaccination and the increased incidence of hypersensitivity reactions associated with receipt of frequent booster injections.[456] Patients convalescing from tetanus infection should complete active immunization because infection often does not confer immunity.

Precautions and Contraindications

A history of having an immediate, severe hypersensitivity reaction to tetanus toxoid-containing preparations that is

severe or anaphylactic in type is a contraindication to receiving further vaccination.[29,39,86,357] Persons who experience Arthus-type hypersensitivity reactions after receiving tetanus toxoid or temperature greater than 39.4°C (103°F) after a previous dose of a tetanus toxoid–containing preparation usually have high serum tetanus antitoxin concentrations and should not be given doses of Td more frequently than every 10 years, even if they have a tetanus-prone wound.[29] If an anaphylactic reaction to a previous dose of tetanus toxoid is suspected, intradermal skin testing may be helpful in determining whether to discontinue tetanus toxoid vaccination.[329] Because tetanus toxoid administration has been associated with recurrence of Guillain-Barré syndrome in rare cases,[320] the decision to give additional doses in persons with a previous history of this syndrome within 6 weeks after receipt of tetanus toxoid should be based on consideration of the benefit of revaccination and the comparative risk for having a recurrence of Guillain-Barré syndrome.[179] No physician-diagnosed cases of anaphylaxis or Arthus reactions or Guillain-Barré syndrome in any adolescent or adult following either Tdap vaccine have been reported.

Varicella Vaccine

In the pre-vaccine era, varicella was endemic in the United States and virtually all persons acquired varicella by the time they reached adulthood. Varicella infection was responsible for an estimated 4 million cases, 11,000 hospitalizations, and 100 deaths each year in the United States.[148] Approximately 90 percent of cases occurred in children, with the highest incidence in children 1 to 6 years old.

After introduction and routine use of varicella vaccine in 1995 the incidence of varicella fell by 90 percent, mortality from varicella declined by 66 percent, and rates of hospitalization for varicella decreased by 80 percent.[289,436,593] However, a high frequency of breakthrough varicella (chickenpox occurring in a previously vaccinated person) in immunized children and continuing outbreaks of varicella in schools and in daycare centers occurred, despite high rates of vaccination.[265] In addition, studies showed that over time the vaccine's effectiveness was less than 90 percent,[497] and in one study of healthy children the rate of seroconversion after one dose of the vaccine was only 76 percent.[412] Therefore, in June 2006, the CDC and the AAP recommended a routine two-dose varicella vaccination policy for children (first dose at 12 to 15 months, second dose at 4 to 6 years) and catch-up vaccinations for children, adolescents, and adults who previously had received only one dose.[42,391]

Since recommendation of a routine second dose of vaccine in 2006, the incidence of varicella has declined further in children. Data show that administration of two doses of varicella vaccine is associated with higher antibody titers (and presumably better protection from varicella).[365] Results from a controlled study of the effectiveness of two doses of varicella vaccine indicate that administration of two doses was highly effective in preventing varicella in the first 2.5 years after implementation of the two-dose schedule to prevent disease.[500] Odds of developing varicella were 95 percent lower for children who received two doses compared with one dose of varicella vaccine.

Preparations

Three varicella-containing vaccines are now approved for use in the United States: varicella vaccine (Varivax), combination MMRV vaccine (ProQuad), and herpes zoster vaccine (Zostavax). Varicella vaccine was licensed in the United States in 1995. It is a preparation of the Oka strain of varicella-zoster virus (VZV) obtained from the vesicle fluid of a healthy child with varicella that has been attenuated by serial propagation in human embryo lung fibroblasts, guinea pig embryonic cells, and human diploid cell cultures. The vaccine contains trace amounts of neomycin, fetal bovine serum, sucrose, residual components of human diploid (MRC-5) cells, and gelatin. The vaccine does not contain preservatives.

Varicella vaccine is lyophilized and stored frozen at –15°C or colder until reconstituted. Any freezer that reliably maintains an average temperature of –15°C and has a separate sealed freezer door is acceptable for storing vaccine. The vaccine also may be stored at refrigerator temperature (2°C to 8°C) for as long as 72 hours before reconstitution. Vaccine stored at 2°C to 8°C that is not used within 72 hours should be discarded. Reconstituted vaccine should be stored at room temperature and discarded if it is not used within 30 minutes.

In September 2005, a combined live attenuated MMRV vaccine was licensed for use in persons aged 12 months through 12 years.[137] The attenuated measles, mumps, and rubella vaccine viruses in MMRV are identical and of equal titer to those in the MMR vaccine. The

titer of Oka/Merck VZV is higher in MMRV vaccine than in single-antigen varicella vaccine. Each 0.5-mL dose contains a small quantity of hydrolyzed gelatin, human albumin, residual components of MRC-5 cells, neomycin, bovine calf serum, and other buffer and media ingredients. Unlike single-antigen varicella vaccine, MMRV vaccine cannot be stored at refrigerator temperature. MMRV vaccine must be stored frozen at an average temperature of −15°C or lower for up to 18 months. Once reconstituted, the vaccine should be used immediately to minimize loss of potency and should be discarded if it is not used within 30 minutes. The diluent should be stored separately at room temperature or in the refrigerator. MMRV vaccine contains no preservative. In May 2006, the FDA approved herpes zoster vaccine for use in persons 60 years of age and older. No indications for use of this vaccine in children exist.

Immunogenicity and Efficacy

Varicella vaccine is highly immunogenic in susceptible children. Seroconversion has occurred in more than 96 percent of children aged 12 months to 12 years after one dose of vaccine.[571] Preexisting antibody, if present at 12 months of age, does not appear to interfere with antibody response. As with other viral vaccines, the antibody response after immunization is lower than that from natural disease. Adolescents and adults have age-related decreases in the ability to develop a primary response to varicella virus.[267] Seroconversion rates of 78 to 82 percent after one dose and 99 percent after two doses have been reported in those older than 12 years.[267,571]

In studies in the United States and Japan, serum antibodies to varicella have been detected for as long as 10 to 20 years after immunization in more than 95 percent of immunized children.[58,333] Antibody concentrations have persisted for at least 1 year in 97 percent of adults and adolescents who were administered two doses of vaccine 4 to 8 weeks apart.[267] Cell-mediated immunity to VZV has been detected in 87 percent of children and 94 percent of adults 5 years after vaccination.[592]

MMRV vaccine was licensed on the basis of equivalence of immunogenicity of the antigenic components, rather than clinical efficacy. Clinical studies involving healthy children aged 12 to 23 months of age indicated that those who received a single dose of MMRV vaccine developed levels of antibody to measles, mumps, rubella, and varicella similar to those of children who received MMR and varicella vaccines concomitantly at separate injection sites.[364]

Varicella vaccine has been demonstrated to be highly effective in preventing varicella in children and in reducing the severity of infection if they do become infected. In pre-licensure clinical trials, vaccine was 70 to 90 percent effective in preventing varicella and more than 95 percent effective in preventing severe disease.[366,564] Several post-licensure studies have shown similar results, with vaccine effectiveness ranging from 83 to 100 percent in preventing varicella and 87 to 100 percent in preventing severe disease.[198,328,541] In follow-up studies, chickenpox has developed in 0.2 to 2.3 percent of vaccinated children per year after exposure to wild-type varicella virus, a rate that does not seem to increase with length of time after immunization.[549] These vaccine failure cases are mild, with fewer skin lesions, lower rates of fever, and faster recovery, and they are less contagious than are moderate to severe cases of varicella.[74,498,549,559] These infections have been termed *breakthrough varicella*.

Although findings of some studies have suggested otherwise, most investigations have not identified time since vaccination as a risk factor for breakthrough varicella. Some, but not all, investigations have identified the presence of asthma, use of corticosteroids, and vaccination at younger than 15 months of age as risk factors for breakthrough varicella.[242,263,328,535,544] Breakthrough varicella infection could be a result of several factors, including interference of vaccine virus replication by circulating antibody, impotent vaccine resulting from storage or handling errors, or inaccurate record keeping. Interference from live viral vaccine administered before varicella vaccine could also reduce vaccine effectiveness. A study of 115,000 children in two health maintenance organizations during 1995 to 1999 found that children who received varicella vaccine less than 30 days after MMR vaccination had a 2.5-fold increased risk for breakthrough varicella compared with those who received varicella vaccine before, simultaneously with, or more than 30 days after receiving MMR.[544] Inactivated vaccines (DTaP, Hib, IPV, and hepatitis B) and OPV did not increase the risk for breakthrough varicella if they were administered less than 30 days before administration of varicella vaccine.

In adults and adolescents who have seroconverted, varicella vaccine provides protective efficacy rates of approximately 70 percent after household exposure. In the remaining 30 percent, attenuated disease with fewer skin lesions and little or no systemic toxicity develops, as in children.[267]

Adverse Events

Varicella vaccine produces relatively few adverse reactions.[501,574] The most common adverse reactions that occur after receipt of varicella vaccine are local reactions, such as pain, soreness, erythema, and swelling. Based on information from the manufacturer's clinical trials of varicella vaccine, local reactions after receiving the first dose are reported by 19 percent of children and by 24 percent of adolescents and adults.[501,574] These local adverse reactions generally are mild and self-limited.

A varicella-like rash at the site of injection is reported by 3 percent of children and by 1 percent of adolescents and adults after receipt of the second dose. In both circumstances, a median of two lesions has been present. These lesions generally occur within 2 weeks and usually are maculopapular rather than vesicular.[501,574]

In post-licensure studies, the adverse event most frequently reported is a mild vesicular rash that occurs in approximately 5 percent of vaccines.[148,266] Most of these generalized rashes occur within 3 weeks, and most are maculopapular. In one study, vesicular rashes that occurred within 2 weeks of vaccination were more likely to be caused by wild-type varicella whereas rashes that

occurred more than 2 weeks after vaccination were more likely to be caused by the Oka vaccine strain.[501]

Systemic reactions are not common. Fever within 42 days of vaccination is reported by 15 percent of children and 10 percent of adolescents and adults. Most of these episodes of fever have been attributed to concurrent illness rather than to the vaccine.

Clinical trials of MMRV that compared events that occurred within 42 days of receiving either MMRV or MMR and varicella vaccine separately in different anatomic sites found the frequencies of local reactions and generalized varicella-like rash similar to those described for varicella vaccine.[364] A temperature of 38.9° C (102° F) or higher within 42 days of vaccination was more common in the MMRV group (22%) than in the group that received MMR and varicella vaccine at different sites (15%). A measles-like rash also occurred more frequently in MMRV recipients (3%) than in the group receiving separate injections (2%). Both fever and measles-like rash usually occurred 5 to 12 days after receipt of vaccination. In a post-licensure study, an increased risk for seizure was seen in children 12 to 23 months of age receiving MMRV vaccine when compared with those who received MMR and varicella vaccines given separately in the 7- to 10-day post-vaccination period.[349]

Varicella vaccine is a live virus vaccine and may result in a latent infection, similar to that caused by wild-type varicella virus. Consequently, zoster caused by the vaccine virus has been reported, mostly among vaccinated children. Based on reports to VAERS, the rate of herpes zoster after varicella vaccination is 2.6 per 100,000 vaccine doses distributed.[148] The incidence of herpes zoster after natural varicella infection in healthy persons younger than 20 years is 68 per 100,000 person-years,[287] and, for all ages, it is 215 per 100,000 person-years.[236] However, these rates should be compared cautiously because the latter rates are based on populations monitored for longer periods than the vaccinees were monitored. Cases of herpes zoster have been confirmed by polymerase chain reaction (PCR) to be caused by both vaccine virus and wild-type virus, a finding thus suggesting that some herpes zoster cases in vaccinees may result from antecedent natural varicella infection.[148,297] The majority of cases of herpes zoster that occur after administration of vaccine have been mild and have not been associated with complications such as postherpetic neuralgia.

Transmission of the vaccine virus occurs rarely and most often from immunocompromised vaccinees. Of the 15 million doses of varicella vaccine distributed, on only three occasions has transmission from immunocompetent persons been documented by PCR analysis.[368,490] All three cases resulted in mild disease without complications. In one case, a child 12 months old transmitted the vaccine virus to his pregnant mother.[379,490] The mother elected to terminate the pregnancy, but fetal tissue tested by PCR was negative for varicella vaccine virus. The other two documented cases involved transmission from healthy children aged 1 year to a healthy sibling aged 4½ months and to a healthy father.[148] Transmission also has occurred from a person with herpes zoster caused by vaccine strain virus.[88] Transmission has not been documented in the absence of a vesicular rash after vaccination. No evidence indicates reversion to virulence of the vaccine strain during transmission; siblings of leukemic vaccine recipients who acquired vaccine virus had mild rash in 75 percent of cases and symptomless seroconversion in 25 percent.[54]

Indications

Both monovalent varicella vaccine and MMRV have been licensed for use for healthy children 12 months through 12 years of age.* Children in this age group should receive two 0.5-mL doses of varicella vaccine administered subcutaneously, separated by at least 3 months. The recommendation for at least a 3-month interval between doses is based on the design of the studies evaluating two doses in this age group; if the second dose inadvertently is administered between 28 days and 3 months after the first dose, the second dose does not need to be repeated.

All healthy children routinely should receive the first dose of varicella-containing vaccine at 12 through 15 months of age. The second dose of vaccine is recommended routinely when children are 4 through 6 years of age (i.e., before a child enters kindergarten or first grade) but can be administered at an earlier age. Because of the minimal potential for increased febrile seizures after the first dose of MMRV vaccine in children 12 through 15 months of age, the American Academy of Pediatrics and the ACIP recommend a choice of either MMR plus monovalent varicella vaccine or MMRV for toddlers receiving their first immunization of this kind.[36,390] Parents should be counseled about the rare possibility of their child developing a febrile seizure 1 to 2 weeks after immunization with MMRV for the first immunizing dose. For the second dose at 4 through 6 years of age, MMRV generally is preferred over MMR plus monovalent varicella to minimize the number of injections. Varicella vaccine should be administered to all children in this age range unless there is evidence of immunity to varicella or a contraindication to administration of the vaccine. A catch-up second dose of varicella vaccine should be offered to all children 7 years of age and older who have received only one dose. A routine health maintenance visit at 11 through 12 years of age is recommended for all adolescents to evaluate immunization status and administer necessary vaccines, including the varicella vaccine.

Individuals 13 years of age or older without evidence of immunity should receive two 0.5-mL doses of varicella vaccine, separated by at least 28 days. The recommendation for at least a 28-day interval between doses is based on the design of the studies evaluating two doses in this age group. For persons who previously received only one dose of varicella vaccine, a second dose is necessary. Only monovalent varicella vaccine is licensed for use in this age group.

Women should be assessed prenatally for evidence of varicella immunity. On completion or termination of their pregnancies, women who do not have evidence of varicella immunity should receive the first dose of

*References 31, 36, 42, 176, 390, 391.

varicella vaccine before discharge from the health care facility. The second dose should be administered 4 to 8 weeks later (at the postpartum or other health care visit). To ensure administration of varicella vaccine, standing orders are recommended for health care settings where completion or termination of pregnancy occurs.

Postexposure Prophylaxis. Data from the United States and Japan in a variety of settings indicate that varicella vaccine is 70 to 100 percent effective in preventing illness or modifying the severity of illness if it is used within 3 days, and possibly up to 5 days, after exposure.[489,558] The ACIP recommends administration of varicella vaccine to persons without evidence of immunity 12 months of age or older, including adults, as soon as possible within 72 hours and possibly up to 120 hours after varicella exposure.[391] Varicella vaccine may prevent or modify disease and should be considered in these circumstances if there are no contraindications to its use. A second dose should be given at the age-appropriate interval after the first dose. Physicians should advise parents and their children that the vaccine may not protect against disease in all cases, because some children may have been exposed at the same time as the index case. However, if exposure to varicella does not cause infection, postexposure immunization with varicella vaccine will result in protection against subsequent exposure. There is no evidence that administration of varicella vaccine during the presymptomatic or prodromal stage of illness increases the risk for vaccine-associated adverse events or more severe natural disease.

In 2006, the ACIP approved a revised definition for evidence of immunity to varicella.[391] Revised criteria for evidence of immunity to varicella includes any of the following:

- Documentation of age-appropriate vaccination
- Preschool-aged children 12 months of age and older: one dose
- School-age children, adolescents, and adults: two doses
- Laboratory evidence of immunity or laboratory confirmation of disease
- Birth in the United States before 1980
- Diagnosis of varicella or verification of history of varicella disease by a health care provider
- History of herpes zoster based on health care provider diagnosis.

Precautions and Contraindications

Varicella-containing vaccines are contraindicated in the following situations: (1) pregnancy, (2) severe febrile illness, (3) known history of anaphylactic reaction to vaccine components, and (4) immunodeficiency states (malignancy, primary immunodeficiency disease, immunosuppressive or corticosteroid therapy, and radiation therapy).*

Varicella vaccine should not be administered to persons who have had an anaphylactic-type reaction to any component of the vaccine, including gelatin and neomycin. Most persons with allergy to neomycin have resulting contact dermatitis, a reaction that is not a contraindication to immunization. Monovalent varicella vaccine does not contain preservatives or egg protein, and although the measles and mumps vaccines included in MMRV vaccine are produced in chick embryo culture, the amounts of egg cross-reacting proteins are not significant. Therefore, children with egg allergy routinely may be given MMRV without previous skin testing.

Varicella vaccine should not be administered routinely to children who have congenital or acquired T-lymphocyte immunodeficiency, including persons with leukemia, lymphoma, and other malignant neoplasms affecting the bone marrow or lymphatic systems, as well as children receiving long-term immunosuppressive therapy. An exception includes certain children infected with HIV, as discussed later. Children with impaired humoral immunity may be immunized.

Immunodeficiency should be excluded before immunization in children with a family history of hereditary immunodeficiency. The presence of an immunodeficient or HIV-seropositive household family member does not contraindicate vaccine use in other family members.

In persons with possible altered immunity, immunization against chickenpox should utilize only monovalent varicella vaccine. The Oka vaccine strain remains susceptible to acyclovir; and if a high-risk patient develops vaccine-related varicella, then acyclovir should be used as treatment.

Before routine immunization of healthy children against varicella was instituted in the United States in 1995, many young children with leukemia were susceptible to chickenpox. Considering the variability in intensity of chemotherapy regimens and the current decreasing incidence of varicella in the United States, these high-risk children should not be immunized routinely. Immunization of leukemic children, if susceptible, without evidence of immunity in remission should be undertaken only with expert guidance and with availability of antiviral therapy, should complications occur.

Live-virus vaccines usually are withheld for an interval of at least 3 months after immunosuppressive cancer chemotherapy has been discontinued. However, the interval until immune reconstruction varies with the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors. Therefore, it often is not possible to make a definitive recommendation for an interval after cessation of immunosuppressive therapy when live-virus vaccines can be administered safely and effectively.

Screening for HIV infection is not indicated before routine VZV immunization. Varicella vaccine should be considered for nonimmune HIV-infected children with a $CD4^+$ T-lymphocyte percentage of 15 percent or greater, especially if they are receiving antiretroviral therapy.[419] Eligible children should receive two doses of monovalent varicella vaccine with a 3-month interval between doses and return for evaluation if they experience a postimmunization varicella-like rash. Hundreds of such HIV-infected children have now been safely immunized in the United States, and the vaccine is tolerated much as it is

TABLE 244-15 **Combination Vaccines Licensed in the United States***

Vaccine†	Trade Name (year licensed)	Age Range	Routinely Recommended Ages
DTaP-IPV/Hib	Pentacel (2008)	6 wk-4 yr	Four-dose schedule at 2, 4, 6, and 15-18 mo
DTaP-IPV	Kinrix (2008)	4-6 yr	Fifth dose of DTaP and fourth dose of IPV
MMRV	ProQuad (2005)	12 mo-12 yr	Two doses, the first at 12-15 mo, the second at 4-6 yr
DTaP-HepB-IPV	Pediarix (2002)	6 wk-6 yr	Three-dose series at 2, 4 and 6 mo
HepA-HepB	Twinrix (2001)	≥18 yr	Three doses on a schedule of 0, 1, and 6 mo
Hib-HepB	Comvax (1996)	6 wk-71 mo	Three-dose schedule at 2, 4, and 12-15 mo

*Excludes measles-mumps-rubella (MMR), DTaP, Tdap, Td, and IPV vaccines, for which individual components are not available. DTaP/Hib (TriHIBit) no longer is manufactured.
†A hyphen (-) between vaccine products indicates that products are supplied in their final form by the manufacturer and do not require mixing or reconstitution by the user. A slash (/) indicates that the products must be mixed or reconstituted by the user.
DTaP, diphtheria–tetanus–acellular pertussis; HepA, hepatitis A; HepB, hepatitis B; Hib, *Haemophilus influenzae* type b; IPV, inactivated poliovirus; MMRV, measles-mumps-rubella-varicella.
Modified from American Academy of Pediatrics. Combination vaccines. In: Pickering LK, Baker CJ, Kimberlin DW, et al, editors. *Red book: 2012 report of the Committee on Infectious Diseases.* 29th ed. Elk Grove Village, Ill.: American Academy of Pediatrics; 2012.

in healthy immunized children. Varicella vaccine has been shown to protect these children not only against varicella but also against developing herpes zoster by preventing infection with wild-type VZV.

Varicella vaccine should not be administered to persons who are receiving high doses of systemic corticosteroids (2 mg/kg/day or more of prednisone or its equivalent or 20 mg/day of prednisone or its equivalent) for 14 days or more. The recommended interval between discontinuation of corticosteroid therapy and immunization with varicella vaccine is at least 1 month. Varicella vaccine may be administered to persons receiving inhaled, nasal, and topical corticosteroids. The results of one small study indicate that two doses of the varicella vaccine in 29 children with nephrotic syndrome between 12 months and 18 years of age generally were well tolerated and immunogenic, including children receiving low-dose, alternate-day prednisone.

Household contacts of immunocompromised persons should be immunized if they have no evidence of immunity to decrease the likelihood that wild-type VZV will be introduced in the household. Transmission of vaccine-strain VZV from healthy persons has been documented in seven instances, resulting in eight secondary cases. Even in families with immunocompromised persons, including persons with HIV infection, no precautions are needed after immunization of healthy children in whom a rash does not develop. Immunized persons in whom a rash develops should avoid direct contact with immunocompromised hosts without evidence of immunity for the duration of the rash.

Receipt of antibody-containing blood products (whole blood, plasma, or parenteral immune globulin) may interfere with seroconversion to varicella vaccine. The length of time that such passively acquired antibody persists depends on the concentration and quantity of the blood product received[359] (see Table 244-12).

Although no direct evidence demonstrates that varicella vaccine is harmful to a pregnant female or her fetus, the vaccine should not be administered to women known to be pregnant or considering becoming pregnant within the month because of the theoretical risk for fetal infection associated with a live virus vaccine. Vaccinated women should avoid conception for 1 month after receiving vaccination. The manufacturer has established a Varicella Vaccination in Pregnancy Registry to monitor the maternal-fetal outcomes of pregnant women inadvertently given varicella vaccine.*

A study of nursing mothers and their infants showed no evidence of excretion of vaccine strain in human milk or of transmission to infants who are breast-feeding. Varicella vaccine should be administered to nursing mothers who lack evidence of immunity.

Reye syndrome has occurred in children infected with varicella who receive salicylates. Whether varicella vaccine may induce Reye syndrome is not known, but the vaccine manufacturer recommends that salicylates not be given within at least 6 weeks after administration of varicella vaccine.

DISEASES FOR WHICH COMBINATION VACCINES ARE AVAILABLE

A number of new and improved vaccines have been introduced over the past 20 years. Incorporation of these vaccines into already complex childhood immunization schedules has posed a challenge. In the 2012 Recommended Immunization Schedule in the United States, a minimum of 22 separate injections are needed to immunize a child from birth to 2 years of age.[46,159] At some visits, the administration of three to five separate injections can be indicated.

Combination vaccines represent one solution to the problem of increased numbers of injections. These vaccines incorporate, into a single product, antigens that prevent several diseases. Combinations licensed in recent years in the United States are shown in Table 244-15.

Licensed combination vaccines can be used whenever any components of the combination are indicated and its

*Varicella Vaccination Pregnancy Registry: reporting may be done online at www.merckpregnancyregistries.com/varivax.html or by telephone at 800-986-8999.

other components are not contraindicated and if licensed by the FDA for that dose in the series.[358] Use of combination vaccines can reduce the number of injections patients receive and alleviate parental concern associated with the number of injections. Potential advantages of combination vaccines include (1) improved vaccine coverage rates, (2) timely vaccination coverage for children who need catch-up vaccination, (3) reduced shipping and stocking costs, (4) reduced costs for extra health care visits necessitated by deferral of vaccination, and (5) facilitation of adding new vaccines into vaccination programs.

Potential disadvantages of combination vaccines include (1) adverse events that might occur more frequently after administration of a combination vaccine compared with administration of separate antigens at the same visit, such as those that occur with the MMRV vaccine and combination DTaP-hepatitis B-IPV vaccine[390,528]; (2) confusion and uncertainty about selection of vaccine combinations and schedules for subsequent doses, especially when vaccinations are given by multiple providers who might be using different products; (3) reduced immunogenicity of one or more components[232]; (4) extra doses of certain antigens in the fixed product (e.g., a provider who uses DTaP-hepatitis B-IPV vaccine will give an extra dose of hepatitis B component); and (5) a shorter shelf-life than the individual component vaccines. The economic impact of the use of combination vaccines is unclear because combination products have the potential for either increased or decreased costs compared with single-antigen component vaccines.

The minimum age for administration of a combination vaccine is the oldest minimum age for any of the individual components; the minimum interval between doses is equal to the greatest minimum interval of any of the individual components. When patients have received the recommended immunizations for some of the components in a combination vaccine, administering the extra antigen(s) in the combination vaccine is permissible if they are not contraindicated and doing so will reduce the number of injections required. However, excessive doses of toxoid vaccines (diphtheria and tetanus) may result in extensive local reactions.

Only combination vaccines licensed by the FDA should be used. Separate vaccines should not be combined into the same syringe for administration together unless such mixing is indicated for the patient's age and is explicitly specified on the FDA-approved product label inserts. Only one combination vaccine (DTaP-IPV/Hib vaccine, marketed as Pentacel) contains separate antigen components for which FDA approves mixing by the user. The safety, immunogenicity, and efficacy of unlicensed combinations are unknown.

In general, licensure of a combination vaccine by the FDA is based on studies demonstrating that the product's immunogenicity (or efficacy) and safety are comparable or equivalent to monovalent or combination products licensed previously. FDA licensure also generally indicates that a combination vaccine may be used interchangeably with monovalent formulations and other combination products with similar component antigens produced by the same manufacturer to continue the vaccination series. For example, DTaP, DTaP/Hib, and future DTaP vaccines that contain similar acellular pertussis antigens from the same manufacturer may be used interchangeably if licensed and indicated for the patient's age.[129] Licensure of a vaccine by the FDA does not necessarily indicate that the vaccine is interchangeable with products from other manufacturers. Such data are more readily available for diseases with known serologic correlates of protective immunity. For diseases without such surrogate laboratory markers, pre-licensure field vaccine efficacy (phase III) trials or post-licensure surveillance generally are required to determine protection.[413] The ACIP prefers that doses of vaccine in a series come from the same manufacturer; however, if this is not possible or if the manufacturer of doses of vaccine given previously is unknown, providers should administer the vaccine that they have available.

VACCINES WITH SELECTIVE INDICATIONS FOR CHILDREN AND ADOLESCENTS

Bacille Calmette-Guérin Vaccine

Effective control of tuberculosis in the United States has been achieved by the early identification and treatment of cases, followed by surveillance of household and other close contacts and institution of appropriate preventive measures for those at high risk for development of disease. In the United States, the mainstay of preventive therapy is isoniazid chemoprophylaxis, which is used in asymptomatically infected persons to prevent the progression of infection to disease. In selected instances, however, the potential for acquiring disease, poor compliance in contacts instructed to take chemoprophylaxis, or failure of chemoprophylaxis may justify the use of immunoprophylaxis.[163] Elsewhere in the world, bacille Calmette-Guérin (BCG) vaccine is used in more than 100 countries and is recommended routinely at birth by the WHO (see Table 244-5).[577] Of primary concern to pediatricians is the risk to an infant born to a tuberculous mother or living within a household with other identified tuberculous individuals.[30]

Preparations

BCG is the only approved vaccine against tuberculosis. BCG is a live attenuated strain derived from *Mycobacterium bovis*. All currently available BCG vaccines are derived from the original strain at the Pasteur Institute in Paris, but they have been propagated by different methods in many laboratories and therefore vary in their immunogenic and reactogenic properties. BCG (Organon Teknika Corporation) is the only vaccine licensed in the United States. Comparative evaluations of this preparation and other BCG vaccines have not been performed. BCG is administered either percutaneously or intradermally. At least 10 new potential vaccines to prevent tuberculosis are in clinical development. Nevertheless, BCG will remain in use in the foreseeable future and may continue to be used as a prime vaccine in a prime-boost immunization schedule in conjunction with

new TB vaccines.[340] BCG preparations instilled in treatment of bladder cancer are not intended to be used as vaccines.[163]

Immunogenicity and Efficacy

BCG is used primarily in young infants in an attempt to prevent disseminated and other life-threatening manifestations of *Mycobacterium tuberculosis* disease. However, BCG does not prevent infection with *M. tuberculosis*. The efficacy of different BCG vaccines seems to be highly variable. Two meta-analyses of published clinical trials and case-control studies concerning the efficacy of BCG vaccines concluded that BCG has relatively high protective efficacy (approximately 80 percent) against meningeal and miliary tuberculosis in children.[206,479] The protective efficacy against pulmonary tuberculosis, however, differed significantly among the studies, thus precluding a specific conclusion. Protection afforded by BCG in one meta-analysis was estimated to be 50 percent.[206]

Adverse Events

Four billion doses of BCG have been administered with a proven safety record.[340] BCG vaccination usually results in scarring at the site of injection. However, the vaccine has been associated uncommonly (1 to 2 percent of vaccinations) with local adverse reactions such as subcutaneous abscess and lymphadenopathy, which are not generally serious. Osteitis affecting the epiphyses of long bones is a rare complication that develops in one per million vaccinees and may occur as long as several years after receiving BCG immunization. The rate may be higher in neonates. Disseminated fatal disease occurs rarely (0.1 to 1 case per million vaccinees), primarily in persons with severely impaired immune systems.[163,360,380,517] Antituberculosis therapy, except for pyrazinamide, is recommended to treat osteitis and disseminated disease caused by BCG. Some experts also recommend treatment of chronic suppurative lymphadenitis caused by BCG. Persons with complications caused by BCG should be referred, if possible, to a tuberculosis expert for management.

Indications

In the United States, administration of BCG should be considered only in limited and select circumstances, such as unavoidable risk for exposure to *M. tuberculosis* and failure or unfeasibility of other methods of control of tuberculosis. The ACIP and the AAP have published recommendations for the use of BCG to control tuberculosis in children.[30,163]

Healthy infants from birth to 2 months of age may be given BCG without tuberculin skin testing; thereafter, BCG is given only to children with a negative tuberculin skin test. In infants and children, BCG immunization should be considered for those who are not infected with HIV in the following circumstances:

- The child is exposed continually to a person or persons with contagious pulmonary tuberculosis resistant to isoniazid and rifampin and the child cannot be removed from this exposure.
- The child is exposed continually to a person or persons with untreated or ineffectively treated contagious pulmonary tuberculosis, and the child cannot be removed from such exposure or given antituberculosis therapy.

Careful assessment of the potential risks and benefits of BCG vaccine and consultation with personnel in local area control programs for tuberculosis are strongly recommended before the use of BCG. When BCG vaccine is given, care should be taken to observe the precautions and directions for administration on the product label.

Skin Test Reactivity

Recipients of BCG should have repeat tuberculin skin tests 2 to 3 months after immunization to establish that tuberculin cellular reactivity has developed. Failure to react dictates the need for repeat BCG vaccination followed by repeat tuberculin testing.[163] The tuberculin reaction to the BCG vaccine available in the United States generally results in 7 to 15 mm of induration after vaccination and diminishes gradually during subsequent years; without revaccination or repeated exposure to *M. tuberculosis*, reactivity usually disappears within 10 years.[163] The size of the area of induration may be correlated with the number of doses of BCG.[317] However, tuberculin skin test sensitivity does not correlate with BCG efficacy.[302] In BCG recipients, differentiating between a tuberculin reaction representing acquired tuberculous infection and persisting postvaccination reactivity is difficult. Because the degree and duration of protection against tuberculous disease afforded by BCG are uncertain, a positive tuberculin reaction always must be suspected to be indicative of disease.

Precautions and Contraindications

BCG vaccine should not be administered to individuals with burns, skin infections, and certain primary or secondary immunodeficiencies, including HIV infection, because of the risk for disseminated BCG disease. The use of BCG also is contraindicated in persons receiving immunosuppressive medications, including high-dose corticosteroids.

In the United States, where the risk for acquiring tuberculosis is low, BCG vaccine should not be administered to children with known or suspected asymptomatic HIV infection.[163,441] However, in populations where the risk for contracting tuberculosis is high, the WHO has recommended that asymptomatic HIV-infected children receive BCG vaccine at birth or shortly thereafter.[577,581] Although no harmful effects of BCG vaccine on the fetus have been documented, women should avoid receiving vaccination during pregnancy.

Cholera Vaccine

In 2009, 45 countries reported 221,226 cholera cases with 4,946 deaths to the WHO, with 98 percent of cases and 99 percent of deaths reported from Africa.[223] In, 2010, an outbreak of cholera occurred in Haiti with over half a million cases and over 7,000 confirmed deaths, the first

epidemic in the Western Hemisphere since the 1991 epidemic in Peru.[4] In contrast, fewer than 300 cases of cholera have been recognized in the United States since the late 1980s.[111] Most cases have occurred in travelers to cholera-affected areas or persons who have eaten contaminated food brought or imported from these areas.[111] Although cholera remains a significant public health concern in African, Asian, and South American countries, even in these countries the risk to U.S. travelers is low. Persons following the usual tourist itinerary that use standard accommodations in countries reporting cholera are at virtually no risk for acquiring infection.[223]

Preparations

As of August 2000, the only cholera vaccine approved for use in the United States was no longer being manufactured or sold. [110] There are two major types of oral vaccines against cholera that have been licensed for commercial use in other countries: killed whole cell-based and genetically attenuated live vaccines. One killed whole-cell vaccine consists of *Vibrio cholerae* O1 with purified recombinant B-subunit of cholera toxoid (WC/rBS; Dukoral; SBL Vaccin AB, Stockholm). Another whole killed cell-based vaccine lacking the B-subunit (WC-only; ORC-Vax; Hue, Vietnam) was manufactured by the government of Vietnam; and although inexpensive to produce, it did not elicit antitoxic immunity. As such, in 2007 it was modified with international efforts to create a low-cost vaccine (Modified WC-only; mORC-Vax; VaBiotech, Vietnam) and to enable its purchase by the United Nations it is also produced in India (Sanchol; Shantha Biotechnics).[503] The other type of vaccine, an attenuated live oral genetically modified *V. cholerae* O1 strain (CVD 103-HgR; Orochol; Berna Biotech, Bern; known as Mutachol in Canada), is not currently being produced.[309]

Immunogenicity and Efficacy

WC/rBS vaccine confers protection specific to *V. cholerae* serogroup O1.[309] Immunization does not protect against *V. cholerae* serogroup O139 or other species of *Vibrio*. Field trials in Bangladesh, Peru, and Sweden have shown that the WC/rBS vaccine confers 85 to 90 percent protection for 6 months in all age groups after administration of two doses, 1 week apart. In Bangladesh, protection declined rapidly after 6 months in young children, but it was still approximately 60 percent in older children and adults after 2 years. The modified killed whole cell–only vaccine had been studied in several trials and found to be both safe and highly effective with seroconversion rates of vibriocidal antibodies ranging from 53 to 91 percent.[53,488,503,520]

Adverse Events

More than 5 million doses of WC/rBS vaccine have been supplied worldwide.[309] According to manufacturer information from clinical trials and postmarketing surveillance, mild gastrointestinal symptoms (abdominal pain, cramping, diarrhea, nausea) are most commonly reported, occurring at a frequency of 0.1 to 1 percent. Serious adverse events, including a flulike syndrome, rash, arthralgia, and paresthesias, are rare, occurring in less than 1 in 10,000 doses distributed. In several randomized controlled trials Sanchol also demonstrate low frequency of mild symptoms and no major adverse events.[53,488,520]

Indications

Routine immunization is not recommended for travelers.[223] Oral cholera vaccines may be considered for those at higher than average risk, such as health care professionals in endemic areas, aid workers in refugee camps, and those traveling to remote areas where cholera epidemics are occurring and access to medical care is limited. At present, no country requires proof of cholera immunization as a condition for entry, and the WHO recommends against such a requirement. Some local authorities, however, may require immunization (to determine local requirements, travelers may consult the embassies of the countries to which they will be traveling).

Limited data on the safety and immunogenicity of the modified whole-cell–based vaccine in children down to 1 year of age appear promising.[488] However, the WC/rBS vaccine is not recommended to be used in children younger than 2 years of age.

Precautions and Contraindications

Oral cholera vaccine should not be administered to persons with a hypersensitivity reaction to any of the vaccine components. Administration of oral cholera vaccine should be postponed for subjects suffering from acute gastrointestinal illness or acute febrile illness.

Japanese Encephalitis Virus Vaccine

Japanese encephalitis (JE) virus, the most important cause of epidemic arboviral encephalitis in Asia, has a wide clinical spectrum, ranging from asymptomatic infection to permanent neurologic sequelae, and a high case-fatality rate of 25 to 70 percent.[423,536] An inactivated mouse brain–derived vaccine has controlled JE virus infection successfully among human populations in Japan, Korea, and Taiwan since 1968.[447] Two other JE virus vaccines have been used widely, primarily in China, an inactivated primary hamster kidney cell–derived vaccine and a live attenuated vaccine.[389]

Preparations

Two JE vaccines are licensed in the United States; an inactivated mouse brain–derived vaccine (JE-VAX [JE-MB]) and an inactivated Vero cell culture-derived vaccine (IXIARO [JE-VC]). JE-MB was licensed in the United States in 1992 for use in travelers aged 1 year and older. In 2006, production of JE-MB was discontinued and all remaining doses expired in 2011.

A new inactivated cell culture–derived vaccine, JE-VC (IXIARO, Intercell Biomedical, UK; distributed by Novartis Vaccines and Diagnostics, Inc., US) was licensed in the United States in 2009 for persons 17 years of age

and older. JE-VC is an inactivated vaccine derived from the attenuated SA14-14-2 JEV strain propagated in Vero cells. Each 0.5-mL dose contains approximately 6 μg of purified, inactivated JEV proteins and 0.1 percent aluminum hydroxide as an adjuvant. The finished product does not include gelatin stabilizers, antibiotics, or thimerosal. The vaccine should be stored at 2°C to 8°C (35°F to 46°F) and should be protected from light.

The primary vaccination series for JE-VC is two doses administered 28 days apart. Each 0.5-mL dose is given by the intramuscular route; this route is different from that of JE-MB, which is administered subcutaneously. JE-VC is supplied in 0.5-mL single-dose syringes. The dose is the same for all persons aged 17 years and older. The vaccine is not licensed for use in persons aged younger than 17 years.

There currently is no JE vaccine that is licensed and available for use in children in the United States. Other JE vaccines are manufactured and routinely used for children in Asia but are not licensed in the United States. Information regarding options for obtaining JE vaccine for U.S. children is available.[168] A partial list of international travelers' health clinics in Asia that administer JE vaccines to children is available online.*

Immunogenicity and Efficacy

No efficacy data exist for JE-VC. The vaccine was licensed on the basis of its ability to induce JE virus–neutralizing antibodies as a surrogate for protection and safety evaluations in fewer than 5000 adults.[495]

Pediatric clinical trials with JE-VC are ongoing in the Philippines, Australia, Europe, and the United States. More information regarding the U.S. clinical trial is available online at the clinical trials website.†

Adverse Reactions

The most common local reactions to JE-VC are pain (33%), tenderness (36%), and erythema (10%), but severe reactions occur in fewer than 1 percent of recipients.[239] Reported systemic adverse events in the 7 days after vaccination usually are mild but include headache (26%), myalgia (21%), influenza-like illness (13%), and fatigue (13%). No serious hypersensitivity reactions or neurologic adverse events were identified among recipients enrolled in the clinical trials. However, because JE-VC was studied in fewer than 5000 adults, the possibility of rare serious adverse events cannot be excluded. Postlicensure studies and monitoring of surveillance data are ongoing to evaluate the safety of JE-VC in a larger population.

Indications

The risk for JE for most travelers to Asia is low but varies on the basis of destination, duration, season, and activities. All travelers to countries with endemic JE should be informed of the risks of JE and use personal protective measures to reduce the risk for mosquito bites. For some travelers who will be in high-risk settings, JE vaccine can further reduce the risk for infection. The CDC recommends JE vaccine for travelers who plan to spend a month or longer in areas with endemic infection during the JE virus transmission season.[10,256] JE vaccine also should be considered for shorter-term travelers if they plan to travel away from an urban area and have an itinerary or activities that will increase their risk for JE virus exposure. Information on the location of JE virus transmission and detailed information on vaccine recommendations and adverse events can be obtained from the CDC.*

Primary immunization with JE-VC consists of two doses administered 28 days apart. The immunization series should be completed at least 1 week before potential exposure to JE virus. If the primary series was administered more than 1 year previously, a booster dose may be given prior to potential reexposure.[238] Data on the response to a booster dose administered more than 2 years after the primary series are not available. Data on the need for and timing of additional booster doses also are not available.

Precautions and Contraindications

A previous severe allergic reaction after a previous dose of JE-VC is a contraindication to administration of subsequent doses.[256] JE-VC contains protamine sulfate, a compound known to cause hypersensitivity reactions in some persons.

Practitioners should use caution when considering the use of JE vaccine in pregnant women. Vaccination with JE vaccines usually should be deferred because of a theoretic risk to the developing fetus. However, pregnant women who must travel to an area in which risk for JE is high should be vaccinated if the benefits outweigh the risks of vaccination to the mother and developing fetus.

Breast-feeding is not a contraindication to vaccination. However, whether JE-VC or JE-MB is excreted in human milk is not known. Because many drugs are excreted in human milk, practitioners should use caution when considering the use of JE vaccine in breast-feeding women.

No data exist on the use of JE-VC in immunocompromised persons or patients receiving immunosuppressive therapies.

Rabies Vaccine

Rabies is a viral zoonosis transmitted in saliva and other tissue of infected mammals. The virus enters the central nervous system of the host and causes an acute, progressive encephalomyelitis that almost always is fatal. Postexposure prophylaxis is possible because of the long incubation period, usually weeks to months, of this infection.

†http://clinicaltrials.gov/ct2/show/NCT01047839?term=Japanese+encephalitis&rank=26.

*Centers for Disease Control and Prevention: wwwnc.cdc.gov/travel/.

Wild animals are the most important source of infection for both humans and domestic animals. Rabid, insectivorous bats carrying variants of the rabies virus have been responsible for nearly all human cases of rabies in the continental United States in recent years. Transmission has been shown to occur from even minor and unrecognized bites from infected bats. Of the 36 human cases of rabies diagnosed in the United States between 1980 and 1997, 21 (58 percent) were associated with bat variants.[123] Wild carnivores, especially skunks, foxes, coyotes, and raccoons, are the terrestrial animals most often infected with rabies. Wildlife rabies occurs throughout the continental United States; only Hawaii remains consistently free of rabies. Domestic animals including dogs, cats, and ferrets also may be infected, with three times as many reports of rabies annually in cats compared with dogs.[113] The likelihood of human exposure to rabies from a domestic animal in the United States is a rare occurrence, a result of effective national rabies control programs. In most other countries (e.g., Asia, Africa, and Latin America), dogs remain the most important potential source of infection. Therefore, international travelers to areas where canine rabies is still endemic have an increased risk for exposure to rabies. Twelve of the 36 human rabies deaths reported to the CDC from 1980 through 1997 appear to have been related to rabid animals outside the United States.[122,438]

Preparations

Three rabies vaccines are licensed commercially for preexposure and postexposure prophylaxis in the United States: human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), and purified chicken embryo cell (PCEC), but only HDCV and PCEC are being produced and available for use. The HDCV and PCEC vaccines are licensed for intramuscular administration. The HDCV product for intradermal use is no longer available. HDCV (Imovax Rabies, Sanofi Pasteur) is derived from the Pitman-Moore strain grown in human diploid cell culture. PCEC (RabAvert, Chiron Corporation-Novartis) is prepared from the fixed rabies virus strain Flury LEP grown in primary culture of chicken fibroblasts.[237] The HDCV and PCEC vaccines each contain the WHO-recommended standard of at least 2.5 IU of rabies virus antigen per 1.0-mL intramuscular dose. Although not licensed for use in the United States, two intradermal rabies vaccines are recommended by the WHO and used in countries where the two tissue culture vaccines (HDCV and PCEC) are prohibitively expensive.[8]

Immunogenicity and Efficacy

Viral neutralizing antibodies are produced within 7 to 10 days, and protective immunity usually persists for 2 years or longer. Although a definitive protective titer has not been identified, the WHO[584] and the CDC adhere to working guidelines for an acceptable response to immunization.[153] The CDC currently specifies complete viral neutralization at a 1:5 or greater titer by the rapid fluorescent-focus inhibition test as acceptable; the WHO specifies 0.5 IU/mL or more as acceptable.

No randomized, placebo-controlled human trials have documented the efficacy of vaccine for preexposure or postexposure prophylaxis. However, substantial field experience, as well as direct evidence from controlled animal studies, demonstrates a protective effect. The paucity of human cases attests to the efficacy of postexposure prophylaxis with the currently recommended vaccine and immune globulin preparations. To date, rabies has not been reported in the United States in any patient who received the currently recommended postexposure measures. Cases of human rabies occurring after postexposure administration of prophylaxis have resulted from failure to adhere to established guidelines, such as those of the CDC or the WHO.[100,241,258,502,562]

Adverse Events

Reactions occurring after administration of HDCV or PCEC vaccine are less serious and less common than those associated with the previously available vaccines.[123] Local reactions at the injection site occur in 30 to 74 percent of injections, and mild systemic reactions such as fever, headache, nausea, abdominal pain, muscle aches, and dizziness occur in 5 to 40 percent of vaccine recipients. In one report, approximately 6 percent of persons had an immune complex–like reaction 2 to 21 days after receipt of the booster dose of HDCV.[103] This systemic hypersensitivity reaction occurred less frequently in persons receiving primary vaccination. The reactions have been associated with the presence of β-propiolactone–altered human albumin in HDCV and the development of IgE antibodies to this allergen.[259]

Indications and Precautions

When used as indicated, both types of rabies vaccine are considered equally safe and effective for both preexposure and postexposure prophylaxis (see the ACIP recommendations).[387,487] Usually, an immunization series is initiated and completed with one vaccine product. No clinical studies have been conducted that documented a change in efficacy or the frequency of adverse reactions when the series is completed with a second vaccine product. Ideally, an immunization series should be completed with the same product unless serious allergic reactions occur. Corticosteroids, immunosuppressive conditions, and concurrent administration of antimalarial agents can interfere with the adequate development of an active immune response. Postvaccination titers should be checked in these circumstances.

For adults, rabies vaccination always should be administered in the deltoid area. For children, the anterolateral aspect of the thigh also is acceptable. The gluteal area never should be used for HDCV or PCEC injections because administration of HDCV in this area results in lower neutralizing antibody titers and decreased immunogenicity.[258]

Postexposure Prophylaxis. The essential components of rabies postexposure prophylaxis are wound treatment and, for previously unvaccinated persons, concurrent administration of human rabies immune globulin (HRIG)

TABLE 244-16 **Rabies Postexposure Prophylaxis for Individuals Not Previously Immunized**

Animal Type	Evaluation and Disposition of the Animal	Postexposure Prophylaxis Recommendations
Wild		
Skunk Fox Raccoon Most other carnivores Bat	Regard as rabid unless animal proven negative by laboratory tests*	Consider immediate vaccination and if not previously vaccinated, use rabies immune globulin.
Domestic		
Dog	Healthy and available for 10 days observation	Persons should not begin prophylaxis unless animal develops clinical signs of rabies†
Cat	Rabid or suspected rabid	Immediately vaccinate
Ferret	Escaped (unknown)	Consult public health officials
Other		
Livestock Small rodents Large rodents (woodchucks and beavers) Lagomorphs (rabbits and hares) Other mammals	Consider individually	Consult public health officials. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies prophylaxis.

*The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

†During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.

Modified from Manning SE, Rupprecht CE, Fishbein D, et al. Human rabies prevention—United States, 2008: recommendations of the Advisory Committee on Immunization Practices. MMWR Recomm Rep 2008;57(RR-3):1-28.

and vaccine (Table 244-16).[387,487] The combination of active and passive immunization is indicated for the treatment of all bite and all nonbite exposures inflicted by animals suspected or proven to be rabid. Recommendations for the management of persons with possible exposure to rabies include giving meticulous attention to thorough cleansing of the wound with soap and water. The decision to give rabies immunoprophylaxis depends on the circumstances precipitating the exposure, the species and condition of the animal inflicting the wound, and the prevalence of rabies in local animal populations. Bite and nonbite exposures, including scratches, abrasions, open wounds, or mucous membranes contaminated with saliva, are considered significant. Because the need for preventive measures is based on these specific circumstances, the local department of health should be consulted promptly concerning the necessity for initiating postexposure prophylaxis.

When possible, the brains of wild animals (skunks, foxes, coyotes, raccoons, and bats), stray dogs or cats, or symptomatic animals implicated in an exposure should be examined in certified laboratories for evidence of rabies. Immunization always should be initiated promptly and discontinued only if laboratory results are negative. Individuals exposed to healthy dogs or cats that are available for observation do not require immediate prophylactic treatment. Implicated healthy domestic dogs or cats should be quarantined and observed for at least 10 days. If symptoms develop that suggest rabies, the exposed individual should begin postexposure prophylaxis, and the brain of the animal should be examined. An unknown or unavailable animal must be regarded as potentially rabid.

Studies conducted in the United States by the CDC have documented that a regimen of one dose of HRIG and five doses of rabies vaccine (1.0 mL for each dose) given on days 0, 3, 7, 14 and 28 was safe and induced an excellent antibody response in all recipients.[387] In March 2010, ACIP changed recommendations to one dose of HRIG with four doses of rabies vaccine (still 1.0 mL for each dose) given on days 0, 3, 7, and 14. The number of doses recommended for persons with altered immunocompetence has not changed; such persons should be administered a 5-dose vaccination regimen (on days 0, 3, 7, 14, and 28) along with one dose of HRIG.[487] If anatomically feasible, the full dose of HRIG (20 IU/kg) should be infiltrated thoroughly in the area around and into the wounds. Any remaining volume should be injected intramuscularly at a site distant from that of vaccine administration. The dose of HRIG should not exceed that recommended and should not be given beyond the seventh day because HRIG can partially suppress active antibody production.

Persons previously fully vaccinated do not require HRIG and should receive only vaccine (two doses 3 days apart) because an amnestic response will occur after the administration of a booster regardless of the antibody titer.[387] Serum for antibody testing should be obtained from persons whose prophylaxis history or immune status is uncertain, and the course of postexposure active and passive immunoprophylaxis as described for nonimmune individuals should be initiated immediately. If serologic testing demonstrates adequate anti-rabies antibody, postexposure prophylaxis may be discontinued.

Once initiated, rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic

adverse reactions to rabies vaccine. Usually, such reactions can be successfully managed with anti-inflammatory and antipyretic agents such as ibuprofen or acetaminophen. When a person with a history of having had serious hypersensitivity to rabies vaccine must be revaccinated, antihistamines can be administered. Epinephrine should be readily available to counteract any anaphylactic reactions, and the person should be observed carefully immediately after receiving vaccination.

Preexposure Prophylaxis. Active immunization should be considered for high-risk groups (i.e., veterinarians, animal handlers and control officers, selected laboratory workers, persons visiting countries where rabies is hyperendemic, and persons whose pursuits may involve frequent contact with rabid animals, such as spelunkers). Persons whose risk for exposure is less but whose access to immediate competent medical care is restricted also should be considered for preexposure prophylaxis. The primary series consists of three doses (1.0 mL per dose) administered on days 0, 7, and 21 or 28, given intramuscularly in the deltoid area. This three-dose series provides long-term protective immunity, and routine serologic testing for rabies antibody after primary immunization is not necessary. For those individuals who may be immunosuppressed, measurement of anti-rabies antibodies should be performed. In the case of continued or frequent exposure, serum samples should be tested every 2 years and a booster dose of rabies vaccine provided when the antibody titer falls below the minimum accepted level.[387]

Precautions and Contraindications

Because of the potential consequences of inadequately treated rabies exposure and because no indication exists that fetal abnormalities have been associated with rabies vaccination, pregnancy is not considered a contraindication to postexposure prophylaxis.[387] If the risk for exposure to rabies is substantial, preexposure prophylaxis also may be indicated during pregnancy.

Persons who have a history of serious hypersensitivity to rabies vaccine should be revaccinated with caution. Although serious systemic, anaphylactic, or neuroparalytic reactions are rare events during and after the administration of rabies vaccines, such reactions pose a serious dilemma for the patient and the attending physician. A patient's risk for acquiring rabies must be carefully considered before deciding to discontinue vaccination. Advice and assistance on the management of serious adverse reactions for persons receiving rabies vaccines may be sought from the state health department or the CDC.

Typhoid Vaccine

Typhoid fever, an acute, life-threatening febrile illness caused by the bacterium *Salmonella enterica* serovar *typhi (S. typhi)*, remains a serious public health problem throughout the developing world. Although disease prevalence varies greatly depending on the specific population studied, current global estimates suggest that 21.6 million cases of typhoid and 200,000 deaths occur annually.[214] In the United States and much of the developed world, typhoid fever has virtually disappeared.[214] Approximately 400 cases of typhoid fever, mostly among travelers, are reported to the CDC each year. Most reported cases in the United States are acquired during travel to developing countries.[335] Therefore, the primary indication for typhoid vaccination in the United States is international travel to an endemic area.[334] In developing countries without safe water and sanitation, mass immunization is a potentially effective strategy to limit both the severity and the impact of typhoid fever.[2]

The changing epidemiology of typhoid fever underscores the importance of vaccination in both international travelers and high-risk populations in endemic regions. Current studies report that the highest incidence rate is now found in children younger than 5 years of age and results in more severe disease than previously.[507,510] *S. typhi* is increasingly resistant to ampicillin, chloramphenicol, and co-trimoxazole, and quinolone resistance is now being reported.[214] Case-fatality rates, which had decreased from 10 percent to 1 percent with appropriate antibiotic therapy,[583] could rise again without safe, effective, and affordable vaccination strategies.

Preparations

The three types of typhoid vaccines are as follows: inactivated, whole-cell vaccines; live attenuated bacterial vaccines; and subunit vaccines.[77] The parenteral, heat-phenol-inactivated, whole-cell vaccine widely used for many years was highly immunogenic but also was highly reactogenic and no longer is available in the United States. It is the only vaccine currently approved for use in children as young as 6 months and is still available in several developing countries because of its affordability, although manufacturing of this vaccine may not be up to international standards.

Two vaccines currently are licensed for use in the United States, an oral live, attenuated vaccine (TY21a, Vivotif Berna) and a purified Vi (virulence) capsular polysaccharide of *S. typhi* vaccine (ViCPS) (Typhim Vi, Aventis Pasteur) for intramuscular use. Table 244-17 provides information on vaccine dosage and administration. The time required for primary vaccination differs for the two vaccines, as do the lower age limits for use in children.

Ty21a is an oral, live attenuated vaccine consisting of a stable mutant, Ty21a, developed by chemical mutagenesis of a pathogenic *S. typhi* strain. This vaccine was licensed in the United States in 1989 for use in adults and children 6 years of age and older and is available as an enteric-coated capsule. The four-dose primary vaccine series (in the United States and Canada, three-dose series in other parts of the world) is administered as one capsule every other day, taken 1 hour before a meal, for a total of four capsules. The capsules should be kept refrigerated (not frozen), and all four doses must be taken to achieve maximum efficacy. Each capsule should be taken with cool liquid no warmer than 37° C (98.6° F), approximately 1 hour before a meal. This regimen should be completed 1 week before potential exposure. The vaccine

TABLE 244-17 **Dosage and Schedule for Typhoid Fever Vaccination**

Vaccination	Age (yr)	Dose/Route of Administration	No. of Doses	Dosing Interval	Boosting Interval
Oral Live Attenuated TY21a Vaccine					
Primary series	≥6	1 capsule*/oral	4	48 hr	N/A
Booster	≥6	1 capsule*/oral	4	48 hr	Every 5 yr
Vi Capsular Polysaccharide Vaccine					
Primary series	≥2	0.50 mL/IM	1	N/A	N/A
Booster	≥2	0.50 mL/IM	1	N/A	Every 2 yr

*Administer with cool liquid no warmer than 37° C (98.6° F).
N/A, Not applicable.
Modified from Bhattarai A, Mintz E. Typhoid & paratyphoid fever. In: Brunette G, editor. *CDC health information for international travel 2012*. New York: Oxford University Press; 2012, p. 323.

manufacturer recommends that Ty21a not be administered to infants or children younger than 6 years of age.

A parenteral subunit vaccine, ViCPS, was licensed in 1994 for use in adults and children as young as 2 years of age. Primary vaccination with ViCPS consists of one 0.5-mL (25 μg) dose administered intramuscularly and should be given at least 2 weeks before potential exposure. The manufacturer does not recommend the vaccine for children younger than 2 years of age.

In circumstances of continued or repeated exposure to *S.* serotype *typhi*, booster doses are recommended to maintain immunity after primary immunization. The optimal booster schedule for either vaccine has not been determined. Current recommendations for revaccination with either vaccine are provided in Table 244-17. No data have been reported concerning the use of one vaccine as a booster after primary immunization with the other.

Efficacy

Although field trials have demonstrated the efficacy of each vaccine, no comparative studies have been performed.[167] For the heat-phenol-inactivated, whole-cell vaccine, efficacy ranged from 51 to 88 percent and lasted for as long as 7 years. The oral, live attenuated Ty21a vaccine stimulates humoral (both serum IgG and mucosal IgA antibodies) as well as cell-mediated immune responses. In trials of the Ty21a vaccine, efficacy ranged from 42 to 96 percent after administration of the initial series of three doses, with the lower efficacies seen in trials from areas with highly endemic disease.[374,508] The optimum schedule for booster immunizations has not been determined for this vaccine. Protective immunity has been shown to persist for at least 7 years in field trials in endemic countries where herd immunity may have an effect.[291] Revaccination is recommended with the same four-capsule regimen every 5 years for as long as continued exposure is likely to occur.

Immunization with ViCPS results in seroconversion, defined as a fourfold rise in serum anti-Vi antibody, in 80 percent of vaccinees within 2 weeks in endemic as well as nonendemic areas.[291,307,351] Because the vaccine is administered parenterally, mucosal immunity does not develop. The efficacy of ViCPS vaccine in clinical trials was 72 percent at 17 months[1] and 64 percent at 21 months[351] after administration of a single dose. A cluster-randomized trial in India, of 37,673 children 2 years of age and older, demonstrated 61 percent effectiveness.[521] Polysaccharide vaccines do not stimulate T cells and cannot establish immunologic memory. Additional doses of ViCPS therefore do not elicit a booster effect. Revaccination with a single dose is recommended every 2 years for persons who remain at risk.

None of the typhoid vaccines approach 100 percent efficacy, and a large inoculum of *S. typhi* can overcome vaccine-induced immunity. Vaccines do not substitute for proper hygiene and appropriate food handling practices.

Adverse Events

Reactions to the oral Ty21a vaccine generally are mild and consist of transient gastrointestinal upset, fever, headache, and occasionally rash; these reactions occur in less than 5 percent of recipients.[167] Adverse systemic effects are reported in less than 1 percent of vaccines, and neither the development of bacteremia nor person-to-person transmission has been reported.[291]

Reactions to the ViCPS vaccine also occur infrequently, being reported in approximately 7 percent of recipients.[167] These reactions include tenderness at the injection site, erythema and induration, fever, and, very rarely, rashes; systemic complaints occur in less than 2 percent.[291] In contrast, reactions to the inactivated, whole-cell vaccine occur more commonly and are more severe; they include fever in as many as 24 percent of recipients, headache, and severe local pain or swelling in as many as 35 percent of vaccinees. Thirteen to 24 percent of vaccinees subsequently have missed school or work.[375]

Indications

Typhoid vaccination in the United States is recommended only for the following groups[77,167]:

- Travelers to areas where typhoid fever is endemic and in whom a risk for exposure is recognized; risk for exposure is greatest with travel to the Indian subcontinent, Latin America, Asia, the Middle East, and Africa*

*For more information, consult the CDC website: www.cdc.gov/travel.

- Persons with intimate exposure to a documented *S. typhi* carrier, such as occurs with continuing household contact
- Laboratory workers who have frequent contact with *S. typhi* and persons living in areas outside the United States with endemic typhoid infection

Vaccination is not recommended for persons attending summer camp or for those in areas of natural disaster or for control of common-source outbreaks. Doses and schedules for the different typhoid vaccines are given in recommendations of the CDC.[77,167]

Contraindications

Ty21a is a live attenuated vaccine and should not be given to immunocompromised patients, including those receiving high doses of corticosteroids and persons with HIV infection.[77,167] Ty21a vaccine also should not be administered during a gastrointestinal illness or concurrent with certain antibiotics. The *2012 Red Book* recommends avoiding antimicrobial therapy for at least 24 hours before the first dose of oral typhoid vaccine through 7 days after the last dose.[28] Reports are conflicting regarding the use of the antimalarial agents atovaquone and proguanil; however, chloroquine and mefloquine do not appear to interfere with the immune response to oral Ty21a. Neither of the available typhoid vaccines should be given to anyone with a history of having severe local or systemic reactions after receiving a previous dose of vaccine.

Ty21a is not approved for children younger than 6 years of age, and ViCPS is not approved for children younger than the age of 2 years. The whole-cell, inactivated vaccine available outside of the United States is approved for use in children between 6 months and 2 years of age.

Information is not available on the safety of these vaccines when they are used during pregnancy. It is prudent on theoretical grounds to avoid vaccinating pregnant women.

Yellow Fever Vaccine

Yellow fever occurs only in sub-Saharan Africa and tropical South America, where it causes an estimated 200,000 cases annually.[481] As a result, yellow fever is an important vaccine-preventable disease among travelers to areas where yellow fever occurs. The yellow fever epidemic zones include Bolivia, Brazil, Colombia, Ecuador, French Guiana, Peru, Venezuela, and much of sub-Saharan Africa. From 1970 to 2009, nine cases of yellow fever were reported in unvaccinated travelers from the United States and Europe who traveled to West Africa or South America.[515] The risk to unvaccinated travelers of acquiring yellow fever probably is increasing because potential zones of transmission of yellow fever are expanding to include urban areas with large populations of susceptible humans and abundant competent mosquito vectors. Vaccination is the most effective preventive measure against yellow fever, a disease that has no specific treatment and may cause death in 20 to 50 percent of patients.[422]

Preparations

Yellow fever vaccines are derived from the original 17D yellow fever vaccine strain. The live attenuated 17D-204 and 17DD yellow fever strains are the yellow fever vaccines most commonly used.[422] The 17D-204 yellow fever vaccine, which is prepared in chick embryos, is licensed in the United States (YF-VAX, Sanofi Pasteur).[515] Primary immunization consists of a single, subcutaneous injection of 0.5 mL of reconstituted, freeze-dried vaccine for both adults and children. The vaccine should be stored at 2°C to 8°C. Because the vaccine does not contain a preservative, reconstituted vaccine that remains unused after 1 hour must be properly disposed.

Immunogenicity and Efficacy

Seroconversion rates of 93 percent have been documented in young children receiving yellow fever vaccine.[588] Immunity develops by the 10th day after primary vaccination. The titer of virus neutralizing antibodies in sera of vaccinees is used as a surrogate for vaccine effectiveness. Immunity acquired from immunization with the 17D strain virus has been demonstrated to persist for more than 10 years.[482,576] Revaccination is required no more frequently than every 10 years.[482]

No human efficacy studies have been performed with yellow fever vaccine. Worldwide, only five cases of yellow fever have been reported in vaccine recipients since yellow fever vaccine has been in use; whether any or all of them were vaccinated properly with appropriately handled yellow fever vaccine is uncertain.[422]

Adverse Events

The 17D-204 and 17DD yellow fever vaccines are among the safest and most effective viral vaccines.[422] Since 1965, approximately 8 million doses of 17D-derived yellow fever vaccine have been administered to U.S. travelers, and approximately 300 million doses have been administered to persons in areas where yellow fever is endemic. Although 2 to 5 percent of persons who receive vaccine report headaches, myalgia, and low-grade fever 5 to 10 days after receiving vaccination, less than 1 percent will report curtailing their usual activities.

Historically, yellow fever vaccine–associated adverse events were seen primarily among infants and presented as encephalitis. However, with the current yellow fever vaccine, serious adverse events associated with vaccine rarely occur, especially in children. A systematic review found that no serious adverse events were reported in four randomized controlled trials of infants and children (n = 1866).[527]

Three well-characterized serious adverse events occur after yellow fever vaccine administration: (1) immediate hypersensitivity or anaphylactic reactions, (2) yellow fever vaccine–associated neurologic disease (YEL-AND), and (3) yellow fever vaccine–associated viscerotropic disease (YEL-AVD). In general, immediate hypersensitivity reactions, characterized by rash, urticaria, or asthma, or a combination of these, are uncommon (incidence < one case/131,000 vaccinees). Unrecognized

allergy to eggs or chicken or to the hydrolyzed gelatin used to stabilize the vaccine may be responsible for hypersensitivity reactions.

YEL-AND is a serious but rarely fatal adverse event. YEL-AND manifests as several distinct clinical syndromes, including meningoencephalitis (neurotropic disease), Guillain-Barré syndrome, acute disseminated encephalomyelitis (ADEM), and bulbar palsy.[107] Meningoencephalitis occurs as a result of direct yellow fever vaccine viral invasion of the central nervous system (CNS) with infection of the meninges and/or the brain. The other neurologic syndromes (e.g., Guillain-Barré syndrome and ADEM) represent autoimmune manifestations in which antibodies and/or T cells produced in response to the vaccine cross react with neuronal epitopes and lead to central or peripheral nerve damage.

Data regarding the specific age and illness onset for the different neurologic presentations can be derived from VAERS reports.[408] Of six reported encephalitis cases, the median age was 54 years (range, 16 to 78 years), and median time to onset after vaccination was 14 days (range, 5 to 24 days). For the six Guillain-Barré syndrome cases, the median age was 53 years (range, 17 to 68 years) and median time to onset after vaccination was 13 days (range, 7 to 27 days). Finally, for the three ADEM cases, the median age was 19 years (range, 18 to 61 years), and median time to onset after vaccination was 15 days (range, 7 to 20 days). Crude estimates in the United States of the reported frequency range from four to eight cases per 1 million doses distributed.

In 2001, a previously unrecognized serious adverse reaction among recipients of YF vaccine was first described. This syndrome previously was reported as febrile multiple organ system failure and now is called yellow fever vaccine–associated viscerotropic disease. YEL-AVD mimics naturally acquired yellow fever disease, with the vaccine virus proliferating and disseminating throughout the host's tissues. As of February 2010, a total of 57 cases of YEL-AVD have been reported to the CDC from 14 countries (Australia, Belgium, Brazil, China, Colombia, Ecuador, France, Germany, Japan, Peru, Spain, Switzerland, the United Kingdom, and the United States). The cases have occurred in association with the different substrains of yellow fever vaccine produced by several manufacturers. On the basis of an analysis of cases for which information is available, YEL-AVD has occurred only after a recipient's first yellow fever F vaccination; no cases of YEL-AVD occurring in persons receiving booster doses of the vaccine have been reported.

Several risk estimates for YEL-AVD have been published. On the basis of VAERS data, the reporting rate of YEL-AVD is three to four cases per 1 million doses distributed.[378,397]

The recognition of these adverse events may be challenging because the neurologic syndromes (encephalitis, myelitis) can be difficult to distinguish from bacterial meningitis, encephalitis, or malaria and the viscerotropic syndrome can be difficult to distinguish from hemorrhagic fevers, viral hepatitis, and many other causes of multisystem failure.

The CDC initiated the YF Vaccine Safety Working Group to guide ongoing investigations of the potential underlying causes of severe adverse events associated with yellow fever vaccines.*

Indications

Yellow fever vaccine is recommended for persons 9 months of age or older traveling to or residing in areas where yellow fever is endemic.[515] Because of the increased risk for development of neurologic complications, infants aged 4 to 8 months should be considered for vaccination only when travel to high-risk areas is required and high-level protection against mosquito exposure is not feasible. Vaccination for international travel to certain destinations is required. To obtain an international certificate of vaccination, a yellow fever vaccine approved by the WHO and administered at a designated yellow fever vaccine center is required. Yellow fever vaccine centers in the United States can be identified by contacting state or local health departments. The International Health Regulations require revaccination at intervals of 10 years. Revaccination may boost antibody titers; however, evidence from several studies suggests that yellow fever immunity persists for at least 30 to 35 years and probably for life.

Precautions and Contraindications

The risk for having adverse reactions appears to be age related.[515] Infants younger than 9 months should not receive yellow fever vaccine because of the increased risk for vaccine-associated neurotropic disease developing in this age group.[10] Immunization should be delayed until an infant is at least 9 months of age. In unusual circumstances, physicians considering vaccinating infants younger than 9 months of age should contact the applicable division of the CDC for advice.†

No adverse effects of yellow fever vaccine on the developing fetus have been demonstrated. Vaccine administration to pregnant women, however, generally is not indicated because the vaccine is a live virus. Pregnant women should be considered for vaccination only when travel to high-risk areas is required and protection against mosquito exposure is not feasible.

Whether this vaccine is excreted in breast milk is not known. No reports exist of adverse events or transmission of the vaccine viruses from nursing mother to infant. As a precautionary measure, vaccination of nursing mothers should be avoided because of the theoretical risk for the transmission of virus to the breast-fed infant. When travel of nursing mothers to high-risk yellow fever endemic areas cannot be avoided or postponed, these women may be vaccinated.

Yellow fever vaccine, which is a live virus vaccine, poses a risk for encephalitis or other serious adverse events to patients with illnesses that commonly result in

†Division of Vector-Borne Infectious Diseases (970-221-6400) or the Division of Global Migration and Quarantine (404-498-1600).

immunosuppression (e.g., acquired immunodeficiency syndrome or HIV infection, leukemia, lymphoma, generalized malignancy), or patients whose immunologic responses are suppressed by drug therapy (e.g., corticosteroids, alkylating drugs, or antimetabolites) or radiation. These patients should not be vaccinated. Family members of immunosuppressed persons, who themselves have no contraindications, may receive yellow fever vaccine. If travel to an epidemic or endemic area is necessary, the patient should be instructed in ways to avoid mosquitoes and given a vaccine waiver letter.

A history of thymus disease has been identified as a contraindication to receiving yellow fever vaccine. Four of the 26 vaccine recipients with YEL-AVD worldwide have had a history of diseases involving the thymus, all of which are extremely rare, a finding suggesting that compromised thymic function (myasthenia gravis, thymoma, previous thymectomy) may be another independent risk factor for viscerotropic disease.[67] Health care providers should ask about a history of thymus disorder when they are screening a patient before administering yellow fever vaccine. For persons with such a history, alternative means of prevention should be recommended, if travel plans cannot be altered to avoid yellow fever–endemic areas.

Persons with a history of systemic anaphylaxis to eggs should not be vaccinated because the vaccines contain egg proteins and on rare occasion may induce immediate allergic reactions. Less severe or local manifestations of allergy to eggs or to feathers are not contraindications to yellow fever vaccine administration and do not warrant performing vaccine skin testing.[18] If international quarantine regulations are the only reason to immunize a patient known to be hypersensitive to eggs, attempts should be made to obtain a waiver. If immunization of an individual with a questionable history of egg hypersensitivity is considered essential because of a high risk for exposure, an intradermal skin test may be given as directed in the vaccine package insert.[515]

Vaccines Related to Bioterrorism

Two vaccines, anthrax and smallpox, are potentially available to protect children against bioterrorist attacks with *Bacillus anthracis* and variola. Neither vaccine is available commercially at this time and does not have indications for children and adolescents in the absence of a bioterrorist attack.[484] The vaccines are reviewed in the relevant disease-specific chapters.

Investigational Vaccines

Routine immunizations for children have virtually eliminated many infectious diseases from the United States. These successes have encouraged research to develop vaccines to prevent other serious viral and bacterial diseases affecting children. A 1985 report by the IOM of the National Academy of Sciences reviewed the benefits that would be associated with the development and use of new and improved vaccines in the United States.[208] The report listed 14 diseases for which vaccines were desirable. A 1999 study by the IOM noted that considerable progress had been made since the 1985 study.[209] Seven of 14 vaccines listed in the 1985 study as domestic priorities for development are now licensed. They include acellular pertussis vaccine, LAIV, and vaccines against hepatitis A and B, *H. influenzae* type b, varicella, and rotavirus.

The 1999 IOM report used a new quantitative model to compare the cost and health benefits of developing candidate vaccines.[209] This model can be used to evaluate the potential impact of a new vaccine on public health. In the 1999 report, the model was used to evaluate diseases for which candidate vaccines were being developed. The report divided 26 candidate vaccines into four groups, from most to least favorable for development. The four vaccines in the top tier include a cytomegalovirus vaccine given to adolescents, a universal influenza vaccine, a group B streptococcus vaccine for high-risk adults and pregnant women, and an *S. pneumoniae* vaccine for infants and seniors. Other diseases for which vaccines would be desirable included *Chlamydia trachomatis*, enterotoxigenic *Escherichia coli*, Epstein-Barr virus, *Helicobacter pylori*, hepatitis C virus, herpes simplex virus, HPV, *M. tuberculosis*, *Neisseria gonorrhoeae*, respiratory syncytial virus, parainfluenza virus, *Shigella*, and groups A and B streptococcus.

Two vaccines listed in the 1999 study are now licensed: pneumococcal conjugate vaccine for infants and HPV vaccine. Candidate vaccines are in human trials for many of the other pathogens listed in the 1999 IOM report. The status of licensure and recommendations for new vaccines is available from the American Academy of Pediatrics *Red Book*, which is available on the organization's website.*

Advances in biotechnology, increased understanding of the virulence factors of infectious agents, and knowledge of the host immune response have led to new approaches for vaccine development.[246] The three general categories of approaches include the following: live vaccines; killed, inactivated, or subunit vaccines; and, most recently, DNA-based vaccines. In addition, newer technologies such as adjuvants or delivery systems and vectors can be applied to improve immunogenicity. Vaccines are being developed by the application of these newer technologies to numerous infectious agents for which vaccines are not currently available, especially those pathogens listed in the 1999 IOM report.

CHAPTER 245

Passive Immunization

Deborah Lehman • Danica J Schulte

GENERAL PRINCIPLES OF PASSIVE IMMUNITY

DEFINITION

Passive immunization is the administration of antibodies to provide immediate protection against a microbial agent, or toxin. In general, passive immunization is used to provide temporary immunity in an unimmunized subject exposed to an infectious disease when active immunization is unavailable (e.g., respiratory syncytial virus [RSV] infection), is contraindicated (e.g., varicella in an immunocompromised child), or has not been given before exposure (e.g., tetanus or rabies).

Passive immunization also is used in the management of certain disorders associated with toxins (e.g., diphtheria), in certain bites (e.g., snake and spider), in drug overdose (e.g., digoxin), as a specific (e.g., Rh_0 [D] immunoglobulin [IG]) or nonspecific (e.g., antithymocyte globulin) immunosuppressant, and in the treatment of certain infectious diseases.

The following several types of preparations are used in passive immunization (Table 245-1):

1. Standard human immune serum globulin (HISG) for general use, which is available in three forms: immunoglobulin (IG) for intramuscular use (IGIM), intravenous use (IGIV), and subcutaneous use (IGSC)
2. Special high-titer IGs with a known antibody content for specific illnesses
3. Animal sera and antitoxins
4. Monoclonal antibodies (see Table 245-2 for nomenclature)

Most of the licensed special IGs are for intramuscular use only. Plasma, serum, and even breast milk also can be used in passive immunization.

Passive immunization is not always effective; the duration is short and variable (1 to 6 weeks), and undesirable reactions may occur, especially if the antibody is of nonhuman origin. High-titer special IGs and IGIVs are identical to regular IGs and IGIVs, except that they are derived from patients hyperimmunized or convalescing from a specific infection or selected from donors with high titers to a specific antigen; they are useful in several disorders in which regular IG and IGIV are of little or no value.

ANIMAL SERA AND ANTITOXINS

Animal sera and antitoxins are derived from the serum of immunized animals, usually horses (equine). Because these sera are foreign proteins, they carry a significant risk for sensitization. Thus, they should be administered only when specifically indicated, after sensitivity tests, and by a physician prepared to deal with a hypersensitivity reaction.

A careful history must be taken before an animal serum is injected. Inquiry must be made about asthma, hay fever, urticaria, and previous injections of animal serum. Patients with a history of asthma, allergic rhinitis, or other allergic symptoms on exposure to horses may be dangerously sensitive to the corresponding serum, and the serum should be given only with the utmost caution.

Sensitivity Tests for Animal Serum

A skin prick test, followed by an intradermal skin test, always should be performed before any injection of animal serum, regardless of whether the patient has had the serum previously.[19] A skin prick test is performed by applying a drop of a 1:100 dilution of the serum in saline to the site of a superficial scratch, prick, or puncture on the volar aspect of the forearm and observing it for 20 minutes. A positive control (histamine phosphate, 0.1%) and negative control (saline) should also be applied. A positive reaction consists of erythema with wheal formation 3 mm greater than the negative control. (*Note:* Previous use of antihistamines may render results of these tests negative.)

If the skin prick test result is negative, an intradermal test is performed by injecting 0.02 mL of a 1:1000 saline dilution; again, positive (histamine phosphate, 0.1%) and negative control tests should be performed. The reaction is read 10 to 30 minutes after the injection and is positive if a wheal appears that is 3 mm greater than the negative control. If the test result is negative, it should be repeated with 0.02 mL of a 1:100 dilution. For persons with a negative history of animal allergy and no previous exposure to animal sera, the 1:100 dilution may be used initially if the skin prick test result is negative.

Although intradermal skin tests have resulted in fatalities, skin prick tests have not, but can still be associated with immediate reactions. Therefore, a skin test never should be performed (nor serum injected) unless a syringe containing 1 mL of 1:1000 epinephrine is within immediate reach and supportive care available.

Skin tests can indicate the probability of sensitivity. However, a negative skin test result is not an absolute guarantee of the absence of sensitivity. Therefore, either a specific history of allergy or a positive skin test reaction

TABLE 245-1 **Selected Antibody Preparations Available for Passive Immunity in the United States**

Product	Abbreviations and Brand Names	Principal Use
Standard Human Immune Serum Globulins for Intramuscular or Subcutaneous use		
Immunoglobulin, intravenous	IGIV, IVIG	Treatment of antibody deficiency, immune thrombocytopenic purpura, Kawasaki disease, other immunoregulatory and inflammatory diseases
Immunoglobulin, intramuscular	IGIM, IG, ISG	Treatment of antibody deficiency; prevention of measles, hepatitis A
Immunoglobulin, subcutaneous	IGSC	Treatment of antibody deficiency
Special Human Immune Globulins for Intramuscular or Subcutaneous Use		
Hepatitis B immunoglobulin	HBIG, HyperHEP B, Nabi-HB, HepaGamB	Prevention of hepatitis B
Varicella-zoster immunoglobulin	VariZIG	Prevention or modification of chickenpox
Rabies immunoglobulin	RIG	Prevention of rabies
Tetanus immunoglobulin	TIG	Prevention or treatment of tetanus
Vaccinia immunoglobulin	VIG, VIGIM	Prevention or treatment of vaccinia, prevention of smallpox
Rh_0(D) immunoglobulin	RhoGAM, MICRhoGAM, HyperRHO S/D, BayRho-D	Prevention of Rh hemolytic disease
Special Human Immunoglobulins for Intravenous Use		
Cytomegalovirus immunoglobulin	CMV-IGIV, CMVIG, CytoGam	Prevention or treatment of cytomegalovirus infection
Hepatitis B immunoglobulin, intravenous	HBIGIV, HepaGam B, Nabi-HB NovaPlus	Prevention of hepatitis B (including liver transplantation)
Vaccinia immunoglobulin	VIGIV	Prevention or treatment of vaccinia, prevention of smallpox
Rh_0(D) immunoglobulin, intravenous	WinRho SDF, Rhophylac	Treatment of immune thrombocytopenic purpura
Botulinum immunoglobulin	BIG, BabyBIG	Treatment of newborn botulism
Animal Sera and Globulins		
Tetanus antitoxin (equine)	TAT	Prevention or treatment of tetanus (when TIG is unavailable)
Diphtheria antitoxin (equine)	DAT	Treatment of diphtheria
Botulinum antitoxins (equine)		Treatment of botulism
Latrodectus mactans antivenin (equine)	Antivenin	Treatment of black widow spider bites
Crotalidae polyvalent antivenin (equine)		Treatment of most snake bites
Crotalidae polyvalent immune Fab (ovine)		Treatment of most snake bites
Micrurus fulvius antivenin (equine)		Treatment of coral snake bites

with horse serum is sufficient reason for special caution. A positive history of sensitivity to horse dander is an indication of the need for extreme caution.

Administration of Animal Serum

If the history and sensitivity test reactions are negative, the indicated dose of serum may be given intramuscularly, with epinephrine at hand.[19] The patient should be watched closely for an hour for adverse reactions.

Intravenous injection may be indicated if a high concentration of circulating antibody is required rapidly, as in botulism or diphtheria. The manufacturer's instructions should be consulted.

If the skin test reaction is positive or a history of allergy to animal serum is present and the need for the serum is unquestioned (and epinephrine is at hand), a procedure commonly referred to as *desensitization* can be undertaken, but any significant desensitization is unlikely to occur. This procedure merely results in establishing temporary tolerance to the serum. Desensitization should be performed by trained personnel with the necessary emergency equipment and drugs immediately available.

Desensitization consists of periodic (at 15-minute intervals) injections or infusions of progressively larger doses of the serum, starting at a very low dose, until tolerance is achieved. Schedules for intravenous and intradermal, subcutaneous, or intramuscular desensitization are given in the *2012 Red Book*.[19] Administration of sera after desensitization has been achieved must be continuous or protection from desensitization is lost rapidly.

TABLE 245-2 **US Adopted Nomenclature Nomenclature for Monoclonal Antibodies***

The suffix -mab is used for all monoclonal antibodies and fragments.	
The following letters preceding -mab identify the product source:	
u	human
e	hamster
o	mouse
i	primate
a	rat
xi	chimeric
zu	humanized
The general disease state subclass for which the monoclonal antibody is used is encoded by the syllables preceding the above:	
Disease or Target Class	
-vir	viral
-bac	bacterial
-lim	immune
-les	infectious lesions

*United States Adopted Name.

Hypersensitivity Reactions to Animal Serum

Hypersensitivity reactions to animal serum may be of the following four general types:

1. Anaphylactic reactions consisting of urticaria or other rashes; respiratory distress with wheezing, dyspnea, cough, hoarseness, or stridor; cardiovascular reactions, including tachycardia, hypotension, arrhythmia, cyanosis, shock, and unconsciousness; and gastrointestinal reactions, such as cramps, diarrhea, and vomiting, all occurring seconds to minutes after an injection has been administered.
2. Acute febrile reactions consisting of moderate or severe hyperpyrexia within 2 hours after an injection has been given.
3. Serum sickness reactions consisting of urticaria, arthritis, adenopathy, and fever occurring hours to days after an injection has been administered, depending on the dose and the presence or degree of previous sensitization (i.e., serum sickness occurs within hours or a few days after the second injection and within 7 to 12 days after the first injection);
4. Delayed reactions of varying nature, including peripheral neuritis, nephritis, Guillain-Barré syndrome, and myocarditis.

Treatment of Hypersensitivity Reactions to Animal Serum

For anaphylactic reactions, 1:1000 epinephrine at a dose of 0.01 mL/kg (maximum dose, 0.5 mL) is given subcutaneously or intramuscularly immediately. If improvement is not achieved immediately, 1:10,000 epinephrine at a dose of 0.01 mL/kg is given intravenously. This dose can be repeated every 10 minutes for up to three doses. The 1-mL 1:1000 epinephrine vials must be diluted 1:10 in physiologic saline (now 1:10,000) and injected slowly at a dose of 0.01 mL/kg. (A 1:10,000 dilution in a 10-mL vial also is available.)

Administration of epinephrine may be repeated in 5 to 15 minutes if the response is not satisfactory. Vasopressors and positive-pressure oxygen are helpful. For severe urticaria or edema, particularly edema of the larynx, intramuscular injection of antihistamines and corticosteroids is indicated. Administration of serum therapy (if necessary) should be resumed 6 to 8 hours later or after all visible signs of reaction have subsided.

Mild febrile reactions (temperatures <39° C [<102.8° F]) are treated with ibuprofen or acetaminophen. Severe febrile reactions can cause seizures and death and should be treated rigorously with sponge baths or other cooling means to reduce the temperature promptly. Serum sickness and serum neuritis generally are treated with corticosteroids.

HUMAN IMMUNE SERUM GLOBULIN

HISG, or gamma globulin, is available in three forms for general use: IGIM, IGIV and IVIG, and IGSC. IGIM is used primarily for the prevention of certain infectious disorders and less commonly for the treatment of antibody immunodeficiencies. IGIV is used in the treatment of primary and secondary antibody deficiencies, many immunoregulatory disorders (e.g., immune thrombocytopenic purpura and Kawasaki disease), and neurologic disorders (e.g., Guillain-Barré syndrome and peripheral neuritis). IGSC is used exclusively for treatment of antibody deficiency.

Intramuscular Immunoglobulin

Pharmacology

IGIM (IMIG) is prepared from pooled human serum by the Cohn alcohol fractionation procedure (thus deriving its alternative name of Cohn fraction II). This procedure and viral inactivation steps remove most other serum proteins, hepatitis viruses, and human immunodeficiency viruses (HIV-1 and HIV-2), thereby providing a safe product for intramuscular injection. It is reconstituted as a sterile approximate 16 percent solution (160 mg/mL) with or without preservative. It contains a wide spectrum of antibodies to viral and bacterial antigens.

IGIM is greater than 95 percent IgG, but trace quantities of IgM and IgA and other serum proteins are present. IgM and IgA are therapeutically insignificant because of their rapid half-lives (~7 days) and low concentrations in IG. IG contains all IgG allotypes (Gm and Km types).

IGIM is approved only for intramuscular or subcutaneous use, and intravenous injection of IGIM generally is contraindicated. IGIM aggregates in vitro to high-molecular-weight complexes (9.5S to 40S) that are strongly anticomplementary. These aggregates probably are responsible for the occasional systemic reactions to IGIM. The incidence of these reactions is increased if the patient has received IGIM previously or if it is inadvertently given intravenously. Agammaglobulinemic boys with affected male relatives (suggesting X-linked inheritance) may have a lower incidence of reactions.[455] Small intradermal injections of IGIM are not of value (except as a placebo), and they are contraindicated.

Intramuscular Immunoglobulin in Antibody Immunodeficiency

IGIM is used infrequently now for IgG replacement therapy in immunodeficiency. The usual dosage is 100 mg/kg/month, about equivalent to 0.7 mL/kg/month of the 16 percent (160 mg/mL) product. Two or three such injections are given at the onset of therapy as a loading dose, often over a 3- to 5-day period. The maximal maintenance dosage should not exceed 20 or 30 mL per week.

Few studies on optimal dosage are available; however, the Medical Research Council Working Party[455] found that 25 mg/kg/week (100 mg/kg/month) was therapeutically equivalent to 50 mg/kg/week but that 10 mg/kg/week was inadequate. Use of IGIM by this route has been supplanted largely by IGIV administration.

IGIM should be given at multiple sites to avoid giving more than 5 mL at any one site (10 mL in a large adult). The buttocks are the preferred site, but the anterior of the thighs also can be used. Tenderness, sterile abscesses, fibrosis, and sciatic nerve injury may result from these injections. The danger of sciatic nerve injury is especially great in a small malnourished infant with inadequate muscle and fat in the gluteal regions. Large doses of IGIM should not be given to patients with severe thrombocytopenia because of the risk for development of hematoma and infection.

The injections are given initially at monthly intervals. If the patient continues to have infection or if a characteristic symptom (e.g., cough, conjunctivitis, diarrhea, arthralgia, or purulent nasal discharge) recurs at the end of the injection period, the interval between doses is decreased to 3 or 2 weeks. Older patients often report that they can tell when their IgG level is low and they need another injection. During acute infections, IgG catabolism increases; so extra injections of IGIM often are given.

Because high serum levels of IgG cannot be maintained, serial IG assays are unnecessary in assessing the effectiveness of treatment. The maximal increase in serum IgG level after a standard IGIM injection will vary from patient to patient and from dose to dose because of different rates of absorption, local proteolysis at the injection site, and distribution within tissues.

An intramuscular injection of 100 mg/kg of IGIM usually raises the IgG serum level by 100 mg/dL after 2 to 4 days.[646] Thus, a recent IGIM injection usually does not obscure the diagnosis of hypogammaglobulinemia.

Intramuscular Immunoglobulin and Special Intramuscular Immunoglobulins for Prevention of Infectious Diseases

IGIM is recommended for prophylaxis of hepatitis A and measles. The recommended doses are found in the sections on these disorders. Special high-titer IGIMs are available for several disorders, such as hepatitis B and varicella. These products are identical to IGIM except for the high titers of specific antibodies. These products also are discussed in the sections on these disorders.

Adverse Effects of Intramuscular Immunoglobulin

Although IGIM is one of the safest biologic products available, rare anaphylactic reactions to intramuscular injections have been reported, particularly in patients requiring repeated injections.[201] The Medical Research Council Working Party[455] noted such reactions in 33/175 patients (19%) treated during a 10-year period. After approximately 40,000 injections, 85 reactions occurred; in eight patients, the injections were stopped as a result of these adverse effects and one death was recorded. Such reactions occurred at any stage of treatment and were unrelated to any particular lot number of IGIM or its anticomplementary activity. Symptoms include anxiety, nausea, vomiting, malaise, flushing, facial swelling, cyanosis, and loss of consciousness. Immediate treatment with epinephrine and antihistamines is indicated.

Persons who experience such reactions should be evaluated before receiving a repeated injection. Skin testing should be performed with several lots of IGIM.[201] A skin test result that is positive for an old but not a new lot of IG may indicate a particular idiosyncratic reaction to a particular lot. Under these circumstances, incremental doses of IG from a new lot are recommended. In other patients, IgE antibodies to IgG develop and result in positive immediate skin test reactions to all IGIM lots. In many other patients, no cause of the reactions can be found. Some of these patients will tolerate gradually increasing doses of IG, particularly if they are premedicated with a nonsteroidal anti-inflammatory agent, diphenhydramine, or corticosteroids. Finally, in a few patients, antibodies have developed to the IgA present in minute quantities in Ig and these IgA antibodies can be detected by serology.[715] This topic is discussed further in the section on adverse effects of IGIV.

Administration of exogenous gamma globulin may inhibit the endogenous synthesis of gamma globulin. In a few patients given IGIM or IGIV from early infancy, we have noted depressed IgG levels that return to normal when the injections are stopped. Amer and colleagues[18] reported decreased IgG levels in premature infants given monthly IGIM injections since birth.

IGIM injections or infusions may inhibit antibody responses to live virus vaccines such as measles or varicella. Siber and associates[618] recommend an interval of 3 months between IVIG or IGIM therapy and administration of live virus vaccines after IG doses of less than 40 mg/kg, an interval of 6 months after doses of 40 to 80 mg/kg, an interval of 8 months after doses of 80 to 400 mg/kg, and an interval of 12 months after large doses (1 to 2 g/kg).

Late side effects after IGIM injections are uncommon occurrences; however, fibrosis of the buttocks or localized subcutaneous atrophy may develop at the site of repeated injections in some patients. Repeated injections of IGIM may result in high levels of mercury from the thimerosal preservative. Although symptoms of acrodynia (mercury toxicity) developed in one patient as a result of such therapy,[441] most remain asymptomatic.

Intravenous Immunoglobulin

Intravenous IG (IGIV, IVIG) is further-treated Cohn fractionated human IG that has been rendered free of complexes and is thus safe for intravenous infusion. These products can be given in large quantities for antibody deficiencies[119]; for several autoimmune, inflammatory, and neurologic disorders[63,193]; and for prevention of transplant rejection.[336,337]

Pharmacology

The first IGIV produced in the United States, in 1981, was Gamimune, a reduced and alkylated 5 percent solution containing 10 percent maltose.[42] The second IVIG produced was prepared by acidification and treatment with pepsin; the lyophilized powder could be reconstituted as a 3, 6, or 12 percent solution (Sandoglobulin). Since then, several other IGIVs have been introduced by different manufacturers.[511]

Several methods of treating Cohn fraction II, including treatment with proteolytic enzymes, ultracentrifugation, chromatography, reduction of sulfhydryl bonds by alkylation, and incubation at low pH, have been used to eliminate high-molecular-weight complexes. Solvent and detergent treatment, pasteurization, and addition of the fatty acid caprylate are used to ensure that viral inactivation occurs,[297] and various stabilizers, such as maltose, albumin, or sucrose, are then added. These variations in manufacturing techniques result in unique characteristics among the different IG products.[511]

Although these products vary somewhat across brands and batches,[628,645] they are for the most part therapeutically equivalent and usually are selected on the basis of cost and convenience. IgG subclass differences exist.[45,628] Antibody titers to specific pathogens also may vary across lots and among different IGIVs.[226] Products differ as to their IgA content, which can be a consideration for patients with anti-IgA antibodies.[45] Premixed liquids have the advantage of convenience because the reconstitution step is not required; however, most solutions must be kept refrigerated.

The IGIV products currently available have all IgG subclasses, adequate serum half-lives (15 to 25 days), wide spectrum of antibody activity, and minimal anticomplementary activity, and they are free of bacterial and viral contamination.[315] Individual donors are checked for viral pathogens, and the final product is checked for sterility. The ability of the fractionation process to remove viral and prion particles is validated by spiking test pools with model pathogens and subjecting them to the same fractionation process used by the plasma pools for human use. Some of them are 5 to 10 percent solutions, and others are lyophilized powders that are reconstituted as 3 to 12 percent solutions.[511,647]

IGIV has several advantages over intramuscular IG, including (1) larger quantities of IgG can be given, (2) high levels of serum IgG can be achieved rapidly, (3) painful intramuscular injections are avoided, (4) tissue pooling and local proteolysis are avoided, and (5) home administration and self-administration are easier to perform.

Administration of Intravenous Immunoglobulin

Administration of IGIV requires venous access, which is sometimes a problem in small children or obese patients. It also requires close monitoring during the infusion, which usually takes 2 to 5 hours.[644] The initial rate is 0.01 mL/kg/min, and if no side effects occur, it can be doubled at 15- to 30-minute intervals to a maximal rate of 0.08 mL/kg/min. Rates above 5 mL/kg/hr (0.08 mL/kg/min) are not recommended. Vital signs should be monitored frequently, and trained personnel should be available to treat adverse reactions. Adverse effects tend to be associated with rapid rates of infusion, in patients with concurrent acute infections, previously untreated patients, or significant time elapse between infusions (>6-week intervals).

IGIV is contraindicated in patients who have had an anaphylactic reaction to IGIV or other blood products. It should be administered with great caution to patients who have IgG subclass deficiencies along with IgA deficiency, anti-IgA antibodies or both.[175]

In responsible, older patients receiving infusions without adverse effects, infusion by home self-administration can be accomplished with considerable cost savings.[51,376,636] However, in most cases, IGIV infusions are performed in the clinic setting or by a home infusion service.

A few investigators have given high concentrations (9% to 12% solutions) infused rapidly during a period of 20 to 40 minutes, which may be tolerated by some patients[594]; however, it should not be done except by experienced personnel equipped to manage adverse reactions.

The brand, lot number, dose, premedication, and any adverse reactions should be recorded. Cold solutions should be warmed to room temperature before administration.

Premedication, such as acetaminophen or diphenhydramine, is often given 30 minutes before infusions are started, particularly for the first infusion or for patients who have had prior reactions. Intravenous hydrocortisone (5 to 6 mg/kg children and 100 to

150 mg/kg in adults) or oral prednisone can be used for prevention of anticipated severe reactions.

Side Effects of Intravenous Immunoglobulins

Certain brands of IVIG may be more reactogenic. In one study involving patients with Kawasaki disease, the two IGIVs used were equivalent therapeutically, but one had a 12-fold (2% vs. 25%) increase in side effects.[569]

Immediate reactions, such as headaches, shaking chills, nausea and vomiting, myalgias, or arthralgias that occur during or shortly after the infusions, are common occurrences.[190,644,646] They may occur in as many as 10 percent of recipients, especially with a first infusion or in individuals with prior reactions.[645] They can be treated by slowing or stopping the infusions and giving nonsteroidal anti-inflammatory drugs, diphenhydramine (1 mg/kg), hydrocortisone, or other steroids. On occasion, switching to a different product (generally one available as a solution) may alleviate the reactions.

Severe Immediate Reactions. Anaphylaxis, shortness of breath, hypotension, hypertension, and other such immediate reactions are uncommon events. Because they rarely involve IgE antibodies, they are termed *anaphylactoid* reactions, and they may be associated with cytokine release, complement activation, or presence of vasoactive substance in the preparations.

Immediate Reactions in IgA-Deficient Patients. An occasional IgA-deficient patient exposed to blood, plasma, or any form of IG may develop IgE anti-IgA antibodies, which may cause a reaction to the small amount of IgA present in Ig.[120] IgG anti-IgA in high titers may cause a complement-mediated anaphylactic reaction.[715] These reactions are extremely rare, and testing patients for IgA deficiency before administration of IGIV is unnecessary. Further, patients with profound antibody deficiency do not develop anti-IgA antibodies. For the sensitized patient, the use of a low-content IgA product or premedication is indicated. Although IgA deficiency is rare, patients with this condition should not be given IGIV unless it is absolutely indicated.

Aseptic Meningitis. Headache is a common occurrence during or after IGIV infusions; however, some patients develop severe headaches 6 to 24 hours after the infusion, sometimes associated with photophobia, stiff neck, and nausea.[351,705] Several of these patients have had spinal taps that show cerebrospinal fluid (CSF) pleocytosis but negative viral and bacterial cultures. The symptoms usually resolve within 96 hours. This complication may recur despite changing brands of IGIV. Most occur when IGIV is used in large doses (e.g., 2 g/kg) for neurologic diseases. Individuals with a past history of migraine may be more susceptible to aseptic meningitis.[600] These patients may tolerate slow infusions of subcutaneous IG.[554,648] Headaches and aseptic meningitis often can be avoided by premedication with steroids or with antimigraine medications.

Renal Complications. Renal failure, usually temporary, has been reported with IGIV, particularly among patients with a history of renal disease.[554,645] When such a problem is anticipated, IGIV should be given slowly at no more than 0.5 g/kg/day.[645]

Thrombotic Complications. Several thrombotic events, including stroke, myocardial infarction, transient ischemic events, and central vein thrombosis, have occurred after IGIV infusions.[645] These events may be associated with high doses and rapid infusion, particularly among patients with preexisting cardiovascular illness, obesity, or immobility.[645,749]

Rare Side Effects. Transient neutropenia, hemolytic anemia, acidosis, and symptoms of hyperviscosity occur rarely.[111,645]

Transmission of Pathogens, Including Hepatitis C, by Intravenous Immunoglobulin

Because IGIV is derived from human donors, a remote chance of transmission of viral or other pathogens exists. Tests of donors and the final products are performed, and newer testing for prions is in place but is not of proved reliability. No instance of HIV infection or Jakob-Creutzfeldt or new-variant (mad cow) Jakob-Creutzfeldt disease have been linked to the use of IGIV. Nonetheless, some patients with immunodeficiency receiving long-term IGIV therapy have developed progressive central nervous system problems.[766]

In the early 1990s, hepatitis C was transmitted by experimental IGIV lots,[408,499] some European preparations,[83,84,406,738] and some commercially available U.S. lots.[141,591] Until the report of an outbreak of hepatitis C in 1994,[141] no U.S. cases of hepatitis associated with a commercially available IVIG had been reported. This transmission occurred shortly after hepatitis C–seropositive donors were excluded from the donor pools used in the manufacture of IGIV.

A plausible explanation for the lack of transmission before this U.S. Food and Drug Administration FDA policy was instituted, is that the hepatitis C antibodies neutralized trace amounts of hepatitis C virus not eliminated during the fractionation. As of October 1994, 137 suspected cases were reported, 88 of which were confirmed.[141,593] Of the 88 patients, 51 (58%) had primary immunodeficiencies and 63 percent eventually became symptomatic.

Bjoro and associates[84] reported that immunocompromised patients had a severe and rapidly progressive course of hepatitis C infection and that responses to interferon (IFN) were poor. Razvi and colleagues[555] have not confirmed this finding in U.S. patients.

Newer manufacturing processes and more rigorous testing seemingly have eliminated the risk for occurrence of hepatitis C transmission.

Intravenous Immunoglobulin and Intramuscular Immunoglobulin Inhibition of Vaccine Antibody Responses

Live-virus vaccines may have diminished immunogenicity when given shortly before or during the several

months after receipt of IG. Specifically, IG administration will inhibit response to measles vaccine for a prolonged period, and inhibition of rubella vaccine also has been demonstrated. The interval between measles vaccine and IG depends on the dose of IG. The inhibition of response to varicella vaccine is not known, and the recommendation is to follow that for measles vaccine administration. IG does not impair responses to oral polio vaccine, oral rotavirus vaccine, or yellow fever vaccine. In contrast to live-viral vaccines, administration of IG has not been demonstrated to cause significant inhibition of immune responses to inactivated vaccines and toxoids. Vaccines should be administered at sites different from those of IGIM. IGIV recipients should be immunized according to the recommended schedule for routine childhood immunization. The pediatric *Red Book* gives detailed recommendations.[19]

Intravenous Immunoglobulin in Primary Immunodeficiencies

Administration of IGIV is indicated for patients with profound primary antibody deficiency (quantitative and qualitative), for patients with combined immunodeficiencies, and for those with secondary immunodeficiency along with significant antibody deficiency (Table 245-3). Regular infusions of IGIV can keep patients with primary antibody immunodeficiencies free of infections for long periods or lessen the severity and frequency of chronic infections.[561]

Patients with hereditary agammaglobulinemias, common variable immunodeficiency, and immunodeficiencies with hyper-IgM clearly benefit from replacement therapy. In combined antibody and cellular defects and in secondary antibody immunodeficiencies, administration of IVIG serves as an important ancillary treatment, but it does not correct the associated T-cell defect or underlying cause of the secondary immunodeficiency.

The recommended dose of IGIV is 400 to 600 mg/kg, usually given every 3 to 4 weeks.[511,644] It should be given every 3 weeks if symptoms develop late in the period between monthly infusions. In general, the trough IgG level should be maintained at approximately 400 mg/dL higher than the pretreatment level, which will normalize the IgG level in most patients (e.g., a level >600 to 1000 mg/dL).

Certain patients who experience continued infections may receive even higher doses (i.e., 600 to 800 mg/kg every 3 to 4 weeks).[199,344] Patients receiving these larger doses may have less frequent sinopulmonary infections, improved pulmonary function, and decreased number of days of illness and hospitalization in contrast to when they received lower doses.[644] Some investigators recommend giving even higher doses (i.e., keeping trough levels above 800 mg/dL) in an effort to prevent pulmonary complications.[199,344]

Some patients with severe disease do not respond to higher doses or more frequent infusions because of permanent tissue damage or deep-seated chronic infection.

IGIV also is used in patients with antibody deficiency but with normal or nearly normal IG levels. Often, these patients need higher or more frequent doses of IGIV because their IgG catabolism is increased as a result of their high serum IgG levels. On occasion, IGIV is indicated in infants with transient hypogammaglobulinemia and persistent infection.

IGIV also has been used in patients with IgG subclass deficiencies, but controlled studies demonstrating efficacy are lacking.[82,376,621]

TABLE 245-3 **Some Immunodeficiencies in Which Human Immune Globulin May Be Beneficial**

Antibody Deficiencies
Congenital agammaglobulinemias
Common variable immunodeficiency
Immunodeficiencies with hyper-IgM
Transient hypogammaglobulinemia of infancy (sometimes)
IgG subclass deficiency with or without IgA deficiency (sometimes)
Antibody deficiency with normal immunoglobulins
Combined Deficiencies
Severe combined immunodeficiencies (all types)
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
Short-limbed dwarfism
X-linked lymphoproliferative syndrome
Secondary Immunodeficiencies
Malignant neoplasms with antibody deficiencies; multiple myeloma, chronic lymphocytic leukemia, other cancers
Protein-losing enteropathy with hypogammaglobulinemia
Nephrotic syndrome with hypogammaglobulinemia
Pediatric acquired immunodeficiency syndrome
Intensive care patients: trauma, surgery, or shock
Posttransplantation
Burns
Prematurity

Special Uses of Intravenous Immunoglobulin in Antibody Deficiencies

A syndrome of polymyositis or chronic encephalitis, or both, caused by persistent enteroviral infection in patients with agammaglobulinemia has been treated successfully with very high doses of IGIV containing specific antibody to the virus.[454,547] However, some patients do not respond.[173]

A very high dose of IGIV (up to 2 g/kg/day) is used occasionally in patients with primary immunodeficiency who develop parvovirus B19 infection, autoimmune disease such as immune thrombocytopenic purpura, or persistent respiratory viral infection.[644]

Subcutaneous Human Immunoglobulin

An alternative to intramuscular injection of IG or infusion of IGIV is slow subcutaneous infusion of IGIM or IGIV.[4,78,79,235] This route is used extensively in Europe, with a 16 percent preservative-free IG. A preservative-free 16 percent product (Vivaglobin) was licensed in 2006 in the United States for subcutaneous use[498]; however, 10 to 12 percent solutions for IGIV also can be used safely.[648]

These products usually are infused into the abdominal wall or thigh with a battery-operated portable infusion

pump.[78,235] The usual dose is 100 to 150 mg/kg/week, the same monthly dose as recommended for IGIV, given at a rate of 0.05 to 0.20 mL/kg/hr. Larger doses and more rapid infusions can be accomplished by using multiple injection sites. If a patient is beginning IGSC therapy and an immediate therapeutic level is sought, loading doses of IGIV at double the monthly maintenance dose can be given 1 week before the start of IGSC. Peak serum IgG levels after IGSC occur 48 to 96 hours after the infusion.

Subcutaneous IG infusions, which can be self-administered, are well tolerated, safe, and preferred by some patients because the adverse reactions are considerably less.[78,235,281] Premedication is rarely needed. Thus, they are more suitable than IGIV for home self-administration.[234,235]

Stiehm and coworkers[648] used this route successfully in patients with poor intravenous access, aseptic meningitis, anaphylactic reactions after receiving IGIV infusions, or rapid gastrointestinal protein loss. Subcutaneous IG has been used safely in IgA-deficient adults with frequent respiratory infections,[281] during pregnancy,[80] and in children.[4]

Rapid administration of subcutaneous infusions of IG has been achieved by using two pumps at four infusion sites and increasing the rate to 20 mL/hr per pump, thereby allowing the entire infusion to be completed in little more than an hour.[235]

Immunoglobulin Administration by Other Routes (Oral, Intrathecal, Aerosol, and Local)

Multiple types of antibody have been given by unusual routes with varying degrees of success. None except intravitreous injection of monoclonal antibody is standard care.

Oral Immunoglobulin

Breast milk is the ultimate oral passive immune agent with preventive benefit for newborns. Oral IG administered to provide antimicrobial activity to the gastrointestinal tract mimics the action of antibody-rich colostrum and breast milk. In humans, little or no ingested IG is absorbed intact into the systemic circulation.[41] Some oral IG traverses the entire gastrointestinal tract undigested, particularly in premature infants.[73] Oral IG may neutralize microorganisms, inhibit colonization, and prevent microbial attachment to the gastrointestinal mucosa.

Rotavirus Infection. Barnes and colleagues[68] fed human IG or placebo for 7 days to premature infants in a nursery in which rotavirus was endemic. Rotavirus-associated diarrhea developed in 6/11 babies given placebo and in 1/14 given oral IG.

Losonsky and coworkers[417] administered oral human IG to two children with severe combined immunodeficiency and chronic rotavirus infection and demonstrated a decrease in the amount of free rotavirus excretion and survival of the IG through the gastrointestinal tract. Kanfer and associates[347] used oral human IG to treat rotavirus infection that occurred after bone marrow transplantation.

Bovine hyperimmune colostral IG enriched in rotavirus antibodies (from immunized cows) also has been used in the prevention of rotavirus infection. Davidson and colleagues[178] prevented rotavirus infection in 55 children admitted to an Australian hospital by administering a 10-day course of bovine colostrum; 9/65 control children became infected.

Turner and Kelsey[690] added at least 360 mL of cow colostrum to the formula of 31 term infants 3 to 7 months of age for an average of 101 days (range, 16 to 202 days). Rotavirus infections occurred in 11 (35%) of the colostrum-fed group and 14 (42%) of the control group, an insignificant difference, but symptomatic infection occurred in 1 (3%) of the infants receiving colostrum and 6 (18%) of the controls.

This product also has been used in two studies of the treatment of rotavirus diarrhea in Bangladesh.[464,588] In both studies, less diarrhea, fewer days of illness, less stool output, and more rapid clearance of rotavirus from the stool were noted. Guarino and coworkers[275] used oral human IG (300 mg/kg) as a single dose and observed more rapid recovery from rotavirus diarrhea.

In sum, oral IG is a promising but unproved agent for the prevention and treatment of rotavirus infection.

Necrotizing Enterocolitis. Eibl and colleagues[198] were able to prevent necrotizing enterocolitis in all 90 infants given oral IG rich in serum IgA. Six cases occurred in 91 control infants. Rubaltelli and colleagues[571] in Italy achieved similar results with oral monomeric IgG.

Cryptosporidial Infection. Bovine colostrum was used successfully to treat cryptosporidial diarrhea in HIV infection.[612] Borowitz and Saulsbury[98] used oral IG successfully to treat cryptosporidial infection in a child with acute leukemia.

Other Diarrheas. Oral human IG has been used in the post–bone marrow transplantation period to prevent the development of viral gastroenteritis[347] and to treat nonspecific diarrhea in immunodeficient patients.[457] Commercial products from bovine colostrum are available in Sweden and India.[227,530]

Considerable experimental study findings in veterinarian medicine are available on other oral IGs.

Aerosolized and Intratracheal Immunoglobulin

Aerosolized and intratracheal IG has been used with encouraging results in experimental models of pneumonia caused by RSV, pneumococci, staphylococci, *Yersinia pestis*, and parainfluenza and influenza viruses.* Aerosolized monoclonal antibodies also are being studied for specific infections, bioterrorist toxins (e.g., anthrax, ricin), and lung immunomodulation.[210,400,541,711]

*References 260, 302, 514, 550, 552, 564.

Rimensberger and colleagues[562] conducted a placebo-controlled trial of aerosolized human IG (not RSV-IVIG) in the treatment of RSV infection. No significant benefit was found, but the treatment was well tolerated.

Heikkinen and coworkers[294] used an IgA-enriched human IG as a nasal spray twice daily for 8 weeks to reduce respiratory infections in children between 1 and 4 years of age attending daycare. A 42 percent reduction was achieved in the 19 children receiving the IG versus the 20 children in the placebo group. The authors suggested that this treatment also may decrease the incidence of otitis media.

Intrathecal Immunoglobulin

Human IG has been used intrathecally for the treatment of viral encephalomyelitis in patients with antibody deficiency.[207] Monoclonal antibodies occasionally are given intrathecally in cancer therapy.[642] The use of antitoxin intrathecally in tetanus is discussed in the section on tetanus.

Other Routes

Local application of antibody has been used in the prevention and treatment of surgical and traumatic wounds.[362,540] Injections of the monoclonal antibody bevacizumab (Lucentis) into the vitrea to treat macular degeneration are under way.[170] Inner ear injection of infliximab, a tumor necrosis factor (TNF) monoclonal antibody, has been used in autoimmune neurosensory hearing loss.[703]

Intra-articular IG was of no clinical benefit to patients with rheumatoid arthritis.[56]

IMMUNOGLOBULIN IN SECONDARY IMMUNODEFICIENCIES

Many chronically ill patients have a primary illness that results in immunosuppression and increased susceptibility to infection. These secondary immunodeficiencies are considerably more common than primary immunodeficiency and are particularly common developments in hospitalized patients. Although most such patients have cellular (T-cell) deficiencies, some have antibody deficiencies either isolated or combined with other immune defects. These patients may have low IG levels, poor antibody responses to antigenic challenge, low levels of natural antibodies that may result from loss of IG, loss of immune cells, or the toxic effect of therapy or infection on the immune system. Table 245-2 lists diseases and conditions in which secondary antibody immunodeficiency can occur.

Laboratory criteria that support the use of IGIV include significant hypogammaglobulinemia (serum IgG <200 mg/dL or total IG [IgG + IgM + IgA] <400 mg/dL), absent or unexpectedly low titers of natural antibodies, absent or poor response to antigenic challenge (e.g., tetanus or pneumococcal vaccines), and lack of an antibody response to the infecting organism.[646] Some of the more common secondary immunodeficiencies with antibody defects are discussed.

Hematologic and Oncologic Diseases

Antibody deficiencies can occur with multiple myeloma, chronic lymphocytic leukemia, lymphoma, and advanced cancer, aggravated by the immunosuppressive agents used in their therapy. A double-blind multicenter study concluded that the prophylactic infusion of 400 mg/kg of IGIV every 3 weeks reduced the incidence of bacterial infections in patients with chronic lymphocytic leukemia.[166] The treatment group had fewer infections with *Streptococcus pneumoniae* and *Haemophilus influenzae*, but no difference was noted in infections caused by other gram-negative bacteria, fungi, or viruses.

This beneficial effect was confirmed in a subsequent study,[231] and although concern has been raised about its cost-effectiveness,[724] IGIV also has been shown to reduce the incidence of infections in patients with multiple myeloma[151] and in those receiving chemotherapy for lung cancer.[596] However, Blombery and colleagues[87] found no benefit in the routine use of peritransplant IVIG to reduce infectious complications in patients with multiple myeloma undergoing autologous hematopoietic stem cell transplant.

Protein-Losing States: Enteropathy, Nephrotic Syndrome, and Plastic Bronchitis

In some pediatric patients, antibody deficiency results from massive proteinuria (nephrosis), diarrhea (protein-losing enteropathy), or loss into the lung (plastic bronchitis) associated with accelerated IgG loss. Most of these patients have minimal trouble with recurrent infection, probably because antibody synthesis is intact and most likely accelerated; however, if the loss of IgG greatly exceeds synthetic capacity, symptomatic severe hypogammaglobulinemia may result. IGIV infusions can be used diagnostically in such cases; a large intravenous infusion, followed by serial measurements of serum IgG levels, can document an accelerated IgG half-life (i.e., <10 days).

These patients are candidates for IGIV therapy if they have recurrent infections or very low IgG levels (e.g., <200 mg/dL). Administration of large and repeated doses of IGIV is necessary. On occasion, antibody infusions will help control the severe diarrhea of protein-losing enteropathy.[128] Subcutaneous IG has been used in this situation because its delayed release into the circulation may result in higher long-term IgG levels than can be achieved with an equivalent IGIV monthly dose.[648]

Intensive Care Patients: Trauma, Surgery, and Septic Shock

Patients undergoing severe stress associated with trauma or extensive surgery have profound exposure and susceptibility to infection and a spectrum of immune deficiencies, including cutaneous anergy, leukocyte dysfunction,

hypogammaglobulinemia, and transiently impaired antibody synthesis.[255,475,741] Bowel stasis and hypotension may promote gram-negative sepsis, endotoxemia, or both, along with the development of severe and often irreversible shock.

Early studies by Ziegler and associates[765] and Baumgartner and colleagues[72] suggested that when antisera to a mutant J5 *Escherichia coli* endotoxin with anti–lipid A activity is used in bacteremic or surgical intensive care unit (ICU) patients, the incidence and severity of severe shock could be reduced. However, Calandra and colleagues,[125] used a human IGIV to J5 *E. coli* in 71 patients with gram-negative infections and shock and could not confirm their results. No differences were found in mortality rates, onset of time to shock, and complications.

Just and coworkers[341] administered IGIV and antibiotics to 50 patients in the ICU thought to have infection and compared their outcomes with 54 control patients who received antibiotics alone. Although no difference in survival occurred, they noted a trend indicating that the IGIV-antibiotic group had a shortened stay in the ICU, a shorter period in which respiratory therapy was required, improved renal function, and a favorable effect on infection. Additionally, Ferrara and colleagues[219] reported that IGIV represents a viable adjunct treatment option for certain cases of drug-resistant bacterial infections, and there was a clear survival advantage with the use of IGIV in adult sepsis syndromes by suppressing inflammation.

Rodriquez and colleagues[565] gave an IgM-enriched IGIV or albumin to 56 patients with sepsis undergoing abdominal surgery and found a reduction of sepsis from 55 to 25 percent. Another multicenter study of 352 postsurgical patients confirmed the observation that standard IGIV (400 mg/kg at weekly intervals) reduced the incidence of infections and shortened the stay in the ICU in contrast to patients treated with placebo or hyperimmune core-lipopolysaccharide IG.[318]

Werdan[730] reviewed the use of IGIV in sepsis and suggested certain specific subgroups may benefit (e.g., postoperative sepsis, septic shock with endotoxinemia, and sepsis with neutropenia). A single-institution study from Egypt suggested that IGIV was of benefit in children younger than 2 years in the ICU who had sepsis.[200]

Studies of IGIV in trauma patients requiring surgery[180,189,253] and in patients with head trauma[741] have shown questionable efficacy.

Monoclonal antibodies to endotoxin have been tested in clinical trials of patients in septic shock, but none was of proved efficacy.[483,731,764] Monoclonal antibody to TNF–α also has shown no efficacy in the treatment of adults with septic shock.[3,163] Monoclonal antibodies to interleukin (IL)-6 or IL-1 receptor likewise have not been effective in the treatment of shock.[237]

Prematurity

All premature infants have low levels of maternally derived IgG at birth, and levels approaching 100 mg/dL will develop in the first months of life in most.[64] These IgG levels may be further depressed by pulmonary disease (with transudation into the lungs), fever and stress (with increased IgG catabolism), and multiple blood sampling.[504] In addition, their sluggish antibody responses, their concurrent IgM and IgA deficiency, and their immature complement, phagocytic, and T-cell systems render low-birth-weight infants extraordinarily susceptible to development of infection.[410]

Attempts to decrease the incidence of infections in premature infants by using periodic IG injections date to the 1960s. Four controlled studies enrolling a total of 363 infants used IG doses of 80 to 240 mg/kg/month during their stay in the nursery (two studies), for 4 months, and for 1 year.[18,165,186,640] In two studies, a slight decrease in the number and severity of infections was noted but no difference in survival. These mixed results suggest that IG at the doses used was not of prophylactic value in these patients.

In the last 2 decades, the increasing rate of survival of premature infants and the availability of IGIV have reawakened interest in the use of antibody to prevent infections in premature infants.

An initial double-blind clinical trial by Baker and colleagues[57] suggested that IGIV at a dose of 0.5 g/kg at frequent intervals in the first weeks of life significantly reduced the frequency of sepsis, particularly that caused by *Staphylococcus epidermidis*. Subsequent studies, however, have not shown a clear benefit.

Meta-analyses of prospective, randomized, placebo-controlled prevention studies (representing 5000 infants) were performed by Jenson and Pollock[328,329] and Ohlsson and Lacy.[505] These studies differed in entry criteria, dose, and brand of IGIV, but most infants weighed less than 2000 g, were given IGIV therapy within the first week of life, and received doses of at least 400 mg/kg/month; culture-proved sepsis was used as an end point. Overall, a slight reduction (3%) was seen in the incidence of sepsis but no difference in mortality rates, length of stay, or other complications of prematurity, such as necrotizing enterocolitis, bronchopulmonary dysplasia, and intraventricular hemorrhage.

Shamin and coworkers[606] gave sufficient IGIV for 6 months to 15 of 30 matched premature infants with severe bronchopulmonary dysplasia to maintain their IgG levels above 400 mg/dL, whereas the untreated infants had levels below 200 mg/dL. The number of infections, notably pneumonia, was significantly reduced in the IGIV group (5 episodes of pneumonia and 4 other infections) in contrast to the control group (15 episodes of pneumonia and 12 other infections). In 2011, a large collaborative study of 113 hospitals in nine countries supported this conclusion. They evaluated the use of IGIV in neonatal sepsis and found no effect on the outcome of suspected or proven neonatal sepsis.[274]

Thus, the evidence to date still supports the 1990 National Institutes of Health (NIH) consensus statement that IGIV should not be given routinely to infants of low birth weight[485] but that it may be of value in selected premature infants at high risk for acquiring infection.

IGIV is sometimes of benefit in premature infants with a history of serious infections and underlying lung disease; most such infants will have hypogammaglobulinemia and

should be regarded as having transient hypogammaglobulinemia of infancy.

Hyperimmune IGIV or monoclonal antibodies enriched in antibodies against specific microbial antigens (e.g., *Staphylococcus aureus*) may be of benefit to certain high-risk newborn and premature infants. Two large multicenter double-blind clinical trials of *S. aureus* hyperimmune human IGs were completed in infants of very low birth weight. One used IG from donors immunized with a staphylococcal vaccine against serotypes 5 and 8 (Altastaph).[76,434] The other used IG from donors with a high titer to C1fA, a staphylococcal fibrinogen-binding protein (Veronate).[88,130,181,353] Neither trial showed a significantly decreased severity or incidence of staphylococcal infections.

Transplantation

Conditioning regimens to eliminate or to reduce the host's hematopoietic and immune systems before transplantation (bone marrow and solid organ) render these patients extremely susceptible to infection, particularly cytomegalovirus (CMV) infections.[691] Thus, IGIV and CMV-IGIV have been used to prevent infection, as well as to modify graft-versus-host disease and prevent solid organ rejection.

Early studies of IGIV therapy after allogeneic bone marrow transplantation were modestly successful in preventing infections, decreasing graft-versus-host reaction, and increasing survival rates.[6,71,167,261,661-663] This effect was less dramatic when CMV infection was controlled by ganciclovir and screening of blood products.[277] Two more multicenter studies showed only a modest or no effect on modifying acute graft-versus-host reactions or mortality rates.[169,743] In single-center studies, CMV-IGIV was of no benefit in CMV-positive lung transplant recipients[384] or liver transplant recipients.[265]

IGIV is of benefit in adult kidney transplant recipients with high titers of human leukocyte antigen (HLA) antibodies resulting in a shorter time to transplantation, reduced HLA antibody titers, and improved allograft survival rates.[336,337]

Burns

Bacterial sepsis, particularly *Pseudomonas* spp. and *E. coli* sepsis, is the leading cause of death in the 300,000 patients hospitalized annually in the United States for burns.[474,475] The protein loss in these patients induces hypogammaglobulinemia in proportion to the severity of the burn. High-dose IGIV prolongs survival in experimentally burned mice infected with *Pseudomonas* spp. and preliminary studies of hyperimmune IG and plasma in human burn patients were encouraging, but proof of efficacy is lacking[359,542,658] (see later discussion on burn infections).

Human Immunodeficiency Virus Infection

INTRAVENOUS IMMUNE GLOBULIN IN IMMUNOREGULATORY AND NEUROLOGIC DISORDERS

High-dose IGIV has immunosuppressive and anti-inflammatory effects that render it a valuable agent in the treatment of several autoimmune, inflammatory, and neurologic disorders (Table 245-4).[193,511] A consensus committee has evaluated these uses in terms of likely efficacy.[511]

High-dose IGIV (1 to 2 g/kg) may work by one or more of the following mechanisms[63,193,623,672]:

1. IGIV may decrease the high levels for a pathogenic antibody (such as may be present in myasthenia gravis or idiopathic thrombocytopenic purpura) by accelerating IgG catabolism. IGIV increases IgG levels acutely and increases its catabolism, thus decreasing pathogenic antibodies present in high concentrations. It also saturates the FcRn receptor, thus inhibiting the recirculation of IgG molecules.[756] IGIV also inhibits antibody synthesis by having a direct effect on proliferating B cells, possibly through activation of the FcRII receptor.[584]
2. IGIV contains anti-idiotypic antibodies that can combine with autoimmune antibodies and remove them rapidly from the circulation, which may be a mechanism by which IGIV reduces anti-HLA antibodies in transplant recipients.
3. IGIV binds to Fc receptors on reticuloendothelial cells and causes an Fc receptor blockade, thus reducing the destruction of antibody-coated cells in the spleen or liver. It is a mechanism for the rapid response to IGIV noted in patients with immune thrombocytopenic purpura. Dimeric IGIV may be particularly effective in causing FcR blockage.
4. IGIV combines with other surface receptors to inhibit cellular activation; for example, in toxic epidermal necrolysis, IGIV prevents Fas-mediated cell death of keratinocytes by blocking the Fas receptor.[707]
5. IGIV may promote solubilization and clearance of pathologic immune complexes, such as may be present in lupus nephritis.
6. IGIV downregulates T-cell immune activation by decreasing inflammatory cytokine release or action. In Kawasaki disease, an immediate damping of the cytokine "storm" occurs after IGIV with this illness.
7. IGIV antibodies neutralize bacterial superantigens and prevent them from activating T cells. It is the probable mechanism for its beneficial effect in toxic shock syndrome.[639,672]
8. IGIV combines with complement components to prevent complement-mediated tissue injury. An example is inhibition of complement-mediated myocyte damage in dermatomyositis.
9. IGIV neutralizes virus or bacterial antigens or toxins that may trigger or cause the disease. An

TABLE 245-4 **Likelihood of Benefit of Intravenous Immunoglobulin in Autoimmune, Inflammatory, and Neurologic Diseases**

Proved Benefit*
Kawasaki disease
Graves ophthalmopathy
Immune thrombocytopenic purpura (e.g., idiopathic)
Dermatomyositis
Post–bone marrow transplantation
Neurologic diseases
  Guillain-Barré syndrome
  Chronic inflammatory demyelinating polyneuropathy
  Multifocal motor neuropathy
  Demyelinating neuropathy with IgM gammopathy

Probable Benefit†
Toxic shock syndrome
Postinfectious thrombocytopenic purpura
Neonatal isoimmune or autoimmune thrombocytopenic purpura
Neonatal isoimmune or autoimmune hemolytic anemia
Autoimmune or isoimmune neutropenia
Autoimmune hemolytic anemia
Toxic epidermal necrolysis
Prevention of antibody-mediated kidney transplant rejection
Autoimmune uveitis
Neurologic diseases
  Polymyositis
  Lambert-Eaton myasthenia syndrome
  Myasthenia gravis
  Stiff man syndrome
  Relapsing-remitting multiple sclerosis

Possible Benefit‡
Anticardiolipin antibody syndrome
Coagulopathy with factor VIII inhibitor
Bullous pemphigoid and other blistering skin diseases
Churg-Strauss vasculitis
Vasculitis with antineutrophil cytoplasmic antibodies
Other vasculitides
Stevens-Johnson syndrome
Severe rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune diabetes mellitus
Posttransfusion purpura
Prevention of allograft rejection in high-risk patients with solid organ transplants
Recurrent spontaneous abortion
Cardiomyopathy
Severe persistent high-dose steroid-dependent asthma
Chronic urticaria
Autoimmune liver disease
Delayed pressure urticaria
Neurologic diseases
  Multiple sclerosis
  Rasmussen syndrome
  Intractable childhood epilepsy
  Demyelinating neuropathy with anti-GAM antibodies
  Acute disseminated encephalomyelitis
  Cerebral infarction with antiphospholipid antibodies
  HTLV-1–associated myelopathy
  Lumbosacral or brachial plexitis
  Paraproteinemic neuropathy
  Opsoclonus-myoclonus
  Postinfectious cerebellar ataxia
  Acute idiopathic dysautonomia

Unproven or No Benefit§
Non–steroid-dependent asthma
Atopic dermatitis
Epidermolysis bullosa acquisita
Hemolytic-uremic syndrome
Thrombotic thrombocytopenic purpura
Pure red cell or white cell aplasia
Acquired von Willebrand disease
Chronic fatigue syndrome
Infantile autism
Acute myocarditis
Chronic graft-versus-host disease
Inflammatory bowel disease
Neurologic diseases
  Inclusion body myositis
  Amyotrophic lateral sclerosis
  Paraneoplastic cerebellar degeneration, sensory neuropathy, encephalitis syndrome (POEMS)
  Sensory neuropathy
  Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)
  Alzheimer's disease

Levels of benefits:
*Controlled studies demonstrate efficacy.
†Several case reports or uncontrolled series are convincing.
‡Preliminary studies are encouraging but incomplete.
§Preliminary studies are limited, equivocal, or negative.
HTLV, Human T-lymphotropic virus; *POEMS,* polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes.

example may be the neutralization of bacterial products in hemolytic-uremic syndrome.
10. IGIV contains substances such as soluble HLA antigens and soluble cytokine receptors that may inhibit immune responses.

The illnesses for which IGIV may be of benefit often are of unknown cause, refractory to standard treatment, somewhat responsive to steroids, and associated with local or generalized immune activation with fever, inflammatory cells, and cytokine release.[501] Large doses of IGIV (e.g., usually 1 to 2 g/kg/day) are necessary and may need to be repeated. IGIV preparations may not always be equivalent in action. Tsai and associates[688] found that certain brands of IGIV were less effective in Kawasaki disease than were others.

If a favorable response does not occur immediately or within a few weeks, it probably will not occur later. Proof of efficacy requires a double-blind study (e.g., as conducted for Kawasaki disease) or dramatic reversal of progressive severe disease (e.g., as noted in some cases of toxic shock syndrome). The use of IGIV in Kawasaki disease is covered in Chapter 77.

MONOCLONAL ANTIBODIES

Monoclonal antibodies specific for a single antigenic epitope have been available for laboratory use for several decades and are used increasingly as therapeutic agents. The first monoclonal antibody, licensed in 1984, was a

murine antilymphocyte antibody (anti-CD3 [OKT3]) used for immunosuppression in transplant recipients. Since then, numerous other monoclonal antibodies have been licensed for treatment, and many others are being studied in the United States and abroad.[124]

Nomenclature and Structure

The generic names of therapeutic monoclonal antibodies have been codified, as summarized in Table 245-2.[124] All end in *mab* or *nab*. Preceding this ending is a one- or two-letter prefix that denotes the animal from which it has been produced (e.g., *o* for mouse, as in muromonab; *u* for human, as in adalimumab).

Two types of monoclonal antibodies contain both human and murine components. Chimeric monoclonal antibodies, designated *xi*, contain the Fab portion of a murine IG and the Fc portion of human IG, usually an IgG1 molecule (e.g., rituximab). Humanized monoclonal antibodies, designated *zu*, have only the antibody-combining site of a murine IG (the complementary determinant region), and the rest of the molecule is a human IgG1 molecule (e.g., omalizumab). Chimeric and humanized antibodies are less antigenic and have a longer half-life than do mouse monoclonal antibodies and thus usually are preferred.

One completely human monoclonal antibody is derived from isolated and recombined human L and H chains (adalimumab).

The final prefix before the source prefix designates the disease for which the antibody is used (e.g., *vir* for viral disease, *lim* for immune modulation, and *tu* for cancer). Examples include palivizumab, omalizumab, and transtuzumab. Sometimes the last consonant is dropped for the sake of pronunciation. The beginning of the generic name is left to the manufacturer, as is, of course, the trade name.

Uses of Monoclonal Antibodies

Therapeutic monoclonal antibodies developed to date are licensed for graft rejection, cancer, autoimmunity (e.g., rheumatoid arthritis, inflammatory bowel disease, and immune cytopenias), thrombosis, infectious disease, multiple sclerosis, asthma and allergy, and macular degeneration. Like many new drugs, monoclonal antibodies also are used for disorders other than those for which they are licensed.

Only one of these antibodies, palivizumab (Synagis), directed against RSV, is used in infectious diseases for the prevention of RSV infection in high-risk infants (see the discussion of RSV).[32] However, monoclonal antibodies to microbial antigens and inflammatory mediators will play an important role in tomorrow's battle with infectious pathogens. For example, monoclonal antibodies to anthrax toxin, staphylococcal antigens, and HIV antigens and coreceptors are being studied.

PASSIVE IMMUNITY IN BACTERIAL DISEASES

Antibodies have been used for a century for the prevention and treatment of infectious diseases (Table 245-5). In bacterial disease, antibodies neutralize toxins, facilitate opsonization, and, with complement, promote bacteriolysis; in viral disease, antibodies block viral entry into uninfected cells, promote antibody-directed cell-mediated cytotoxicity by natural killer cells, and neutralize virus alone or with the participation of complement.

Before the use of antibiotics, antibodies were the only specific agents for the treatment of certain infections. Although this role has been supplanted largely by antibiotics, antibody still has a crucial role in the treatment of certain infectious diseases (see Table 245-4). The remainder of this chapter discusses the roles of antibody in prevention and treatment of bacterial and viral diseases. Other reviews are available.[132,133,405]

ANTHRAX

Anthrax is a rare but serious infectious disease, predominantly of ruminant animals, caused by an aerobic gram-positive rod, *Bacillus anthracis*.[134,423,424] Humans can be infected through the skin (cutaneous anthrax), by ingestion (gastrointestinal anthrax), or by inhaling the spores (inhalational anthrax).[424] Inhalational anthrax results from prolonged exposure to animal hides or carcasses and infected soil or, rarely, by deliberate spore exposure in the bioterrorism setting, as occurred in 2001 when anthrax spores were sent through the U.S. mail.[331,423]

After inhalation, the spores are ingested by alveolar phagocytic cells and transported to regional nodes, where they germinate and release exotoxins (lethal toxin and edema toxins), which damage cell membranes, increase capillary permeability, initiate pulmonic changes, and ultimately lead to shock and cardiovascular collapse.

A vaccine is available for individuals at high risk for exposure and the military. It is effective against cutaneous anthrax but is of unproved efficacy against inhalational anthrax.[330] Other vaccines are currently in development.[103]

Before the antibiotic era and as early as 1903, anthrax antitoxin (usually equine) was used in therapy for anthrax.[255,374] An antitoxin would be of value in a bioterrorism attack, both before exposure and after exposure. The Centers for Disease Control and Prevention (CDC) and the NIH are collecting plasma units from military recruits and volunteers immunized with the anthrax vaccine[206] to develop a human high-titer IGIV from these donors.[135,735]

Several monoclonal antibodies against anthrax antigens have been produced.* The best studied is a human monoclonal antibody 5H3 (raxibacumab).[154] Raxibacumab is a human IgG1λ monoclonal antibody directed against

a component of the anthrax toxin. It was shown to be safe and well tolerated intravenously and intramuscularly in human volunteers and provided good antibody titers with a half-life of 15 to 19 days.[660] Two animal efficacy studies demonstrated that a single dose of raxibacumab, given in the absence of antibiotics, improved survival rates up to 64 percent, even when administered after animals were already showing clinical symptoms of inhalation anthrax.[461] In 2009, 20,000 doses of raxibacumab were delivered to the U.S. Strategic National Stockpile and later that year an additional 45.000 doses were made available. In 2012 the FDA approved raxibacumab as treatment in combination with antibacterial drugs, for inhalational anthrax. Raxibacumab was also approved for prevention of inhalational anthrax in instances when other therapies are not available nor appropriate. Raxibacumab is supplied by the U.S. government.

Administration of anthrax IG (AIG) to a 44-year-old man with naturally occurring inhalation anthrax demonstrated subsequent decrease in plasma and pleural fluid lethal factor and increase in antiprotective antigen IgG noted.[718]

Recommendation

In addition to raxibacumab, a limited supply of immune plasma is stockpiled by the U.S. army and is available through an emergency investigational new drug (IND) protocol. This supply would be used in conjunction with antibiotics and with vaccine, the latter to provide immunity after metabolism of the antibody. Immunotherapeutics should be considered for patients with severe systemic illness or lack of clinical response to standard therapy.[643]

BOTULISM, BOTULINUM ANTITOXIN, AND BOTULISM IMMUNOGLOBULIN

Botulism, a severe paralytic poisoning, results from ingestion or absorption of neurotoxins or spores from *Clostridium botulinum*. Several clinical variants are recognized: food poisoning from ingestion of contaminated canned food, wound botulism from a contaminated local infection, inhalational botulism among individuals working with the toxin or in bioterrorism,[47] infant botulism from ingestion of *C. botulinum* spores, and adult-type infant botulism in adults with preexisting gastrointestinal disease. In the last two types, ingested spores multiply in the gastrointestinal tract and produce toxin, which, following absorption, results in a paralytic disorder.[77,136]

Botulism resulting from cosmetic use of an unapproved botulinum toxin A has been reported.[156,637]

Seven immunologic types of *C. botulinum*, designated A through G, have been identified, each elaborating an immunologically distinct toxin. Almost all human botulism has resulted from the ingestion of toxins A, B, and E; toxin E is usually associated with fish and marine mammal products.[378,379,608]

Japanese studies, reviewed by Dolman and Iida,[187] indicate that antitoxin therapy is effective for type E botulism. The mortality rate associated with type E botulism was 49 percent in 135 untreated cases and 3.5 percent in 85 antitoxin-treated cases.

Tacket and associates[668] noted that 46 patients who had type A foodborne botulism and who received trivalent antitoxin had a lower mortality rate (27%) than 13 patients who did not receive antitoxin (46% mortality). Early antitoxin administration resulted in a shorter clinical course.

The presence of toxin in the blood long after the appearance of clinical symptoms or the ingestion of toxin gives theoretical support to the use of antitoxin to prevent further binding of toxin to tissue. Some antitoxin remains in the circulation for more than 30 days, thus indicating that a single initial dose is adequate therapy.

Equine antitoxins to types A, B, and E are the primary antitoxins available in the United States. The decision to use antitoxin is complicated by its unknown efficacy and its side effects, but approximately 80 percent of patients with ingestion-type botulism receive antitoxin.[608]

For information on infant botulism, see Chapter 146.

Recommendations

All forms of botulism, except for infant botulism, are treated with a new heptavalent botulinum antitoxin (HBAT) that now replaces the previously available bivalent antitoxin AB and monovalent antitoxin E. HBAT contains equine-derived antibody to the seven known botulinum toxin types (A to G). The administration of HBAT requires an FDA IND treatment protocol. Suspected cases should be immediately reported to local and state health authorities, and further guidance is available from the CDC's 24-hour hotline.*[,145] Additional information regarding the CDC botulism treatment program is available on the CDC website.† Administration of HBAT should occur only after testing for sensitivity to horse serum because of the risk for hypersensitivity reactions, including anaphylaxis and serum sickness.[19,20,136,608]

Antitoxin also can be given prophylactically to individuals known to have ingested contaminated food. The risk for development of serum reactions (~10%) must be weighed against the risk for contracting the disease.

A 5-year, placebo-controlled, double-blind trial of human botulinum intravenous IG (BIG) for the treatment of infant botulism showed a significant reduction in hospital days, mechanical ventilation, tube feedings, and days of hospitalization in the BIG recipients, with considerable cost savings and minimal adverse events.[48] Three retrospective studies demonstrated similar decreases in the listed interventions.[682,689,693] BIG should be started as soon as possible after the illness is suspected and is available through the California Infant Botulism Treatment and Prevention Program.‡

OTHER CLOSTRIDIAL INFECTIONS

Clostridium difficile Infections

Clostridium difficile is a ubiquitous spore-forming anaerobe often involved in antibiotic-associated diarrhea and pseudomembranous colitis.[20,21] Severity of the disease can range from an asymptomatic carrier state to fulminant colitis with toxic megacolon. Toxic strains of *C. difficile* release two antigenically distinct toxins, both of which have potent cytotoxic and inflammatory properties.[162] Infection generally leads to an antibody response to the toxins, and most individuals older than 2 years of age have the antibodies; thus, *C. difficile* antibodies are present in IGIV preparations.[581]

High levels of IgG antibodies acquired after colonization are associated with the asymptomatic carrier state; individuals who have persistent diarrhea have

*Centers for Disease Control and Prevention 24-hour hotline: 770-488-7100.

†Centers for Disease Control and Prevention botulism treatment website: http://www.bt.cdc.gov/agent/botulism.

‡Instructions for obtaining botulinum intravenous immunoglobulin from the California Infant Botulism Treatment and Prevention Program can be found at http://www.infantbotulism.org/.

significantly lower serum IgG but not IgA to toxin A.[398] Several patients have been identified with relapsing symptomatic disease who have low IgG antibody levels to toxin A.[290,407] Some of these patients had low levels of IgG[407] or IgG1 subclass deficiency.[290] and were treated successfully with IGIV. Since the initial use of IGIV to treat patients with recurrent disease, multiple studies have demonstrated that IGIV contains neutralizing antibodies to toxin A and toxin B.

IGIV treatment of individuals with severe disease, including sepsis, abdominal distention with ileus, and toxic megacolon, also has been reported.[339] The development of an IG preparation derived from volunteers immunized with *C. difficile* toxoid vaccine has the potential to provide higher titer-specific antibodies for treatment of recurrent or refractory *C. difficile* infection. The mechanism thought to be responsible for the protective effect of IGIV is the binding and neutralization of toxin A by IgG anti-toxin A antibodies.[2]

Oral administration of a bovine IgG concentrate was shown effective in preventing diarrhea and death in hamsters when challenged with *C. difficile* infection.[361] However, further investigation into such an approach in humans has not been successful.[360]

Recombinant monoclonal therapeutics have been developed and shown in a randomized, double-blind, placebo-controlled study done at 30 sites in the United States and Canada to significantly reduce the recurrence rate of *C. difficile* disease (25% in the placebo group vs. 7% in the intervention group) There was no demonstrable difference in symptom severity or duration of the initial episode of diarrhea.[420]

Recommendations

Patients with refractory *C. difficile* infections (with or without a global antibody deficiency) can be treated with 300 to 500 mg/kg of IGIV every 1 to 3 weeks as adjunct therapy.[339,453,733,734] Such therapy has been shown to increase antitoxin levels, to control diarrhea, and to prevent relapses during the treatment period.[407,581] However, controlled trials have not been conducted and therefore this use of IGIV is unproved.[333,339]

Studies with an oral anti–*C. difficile* bovine IG for both treatment and prevention have been shown to provide anti–toxin A neutralizing activity, and further development may provide a therapeutic alternative to IV therapy.[723]

Gas Gangrene *(Clostridium perfringens)*

Treatment of gas gangrene with equine antitoxin to *Clostridium perfringens* was of unproved efficacy and no longer is available. Food poisoning caused by *C. perfringens* is self-limited and is not treated with antitoxin.

Tetanus *(Clostridium tetani)*

See the later discussion on tetanus, tetanus antitoxin, and tetanus IG.

DIPHTHERIA AND DIPHTHERIA ANTITOXIN

Diphtheria is caused by toxigenic strains of *Corynebacterium diphtheriae* and occasionally *Corynebacterium ulcerans*. Diphtheria is exceedingly uncommon now because of widespread immunization, but a massive epidemic in the countries of the former Soviet Union occurred in the 1990s, with many fatalities.[343,712]

The adverse consequences of diphtheria result from the toxin elaborated and absorbed from the diphtheritic membrane. This toxin acts locally by perpetuating membrane formation and is distributed via the bloodstream to the heart, nervous system, kidney, and other organs. The larger the membrane, the more toxin that is elaborated; more toxin is elaborated from membranes coating the pharynx and tonsils than from one involving the larynx and trachea.

Diphtheria toxin is present in three forms: (1) circulating and unbound, (2) loosely bound to tissues, and (3) firmly bound to tissues. Antitoxin neutralizes circulating toxin and competes with and partially neutralizes loosely bound toxin but has no effect on tissue-bound toxin. Thus, optimal passive immunity must be initiated at an early stage of the disease by the intravenous route so that toxin can be intercepted before it becomes tissue bound.

In the 1890s, diphtheria antitoxin was used successfully to prevent spread to newly admitted pediatric patients and nurses.[209]

Antitoxin of animal origin remains the mainstay of treatment, as it was in the preantibiotic era. Diphtheria was the first illness in which antiserum was used as standard therapy. In 1901, Emil von Behring was awarded the first Nobel Prize in Medicine for this achievement. Fibiger[220] proved the efficacy of diphtheria antitoxin in 1898 when he showed that 5/204 patients given horse antitoxin died, whereas 14/201 not given antiserum died. Paschlau[527] demonstrated the importance of early administration of antitoxin in 1949; the fatality rate of 197 cases treated within 48 hours was 1.96 percent versus 8.9 percent when treatment was delayed until the fourth or fifth day. Other authors have noted similar findings.[675,676]

Tasman and associates[675,676] emphasized the importance of intravenous administration of antitoxin because rapid achievement of high blood levels results in rapid neutralization of antitoxin and the appearance, within 30 minutes, of antitoxin in saliva. They showed that the mortality rate and the severity of the myocarditis and neuritis in experimental diphtheria in guinea pigs could be reduced by giving antitoxin intravenously rather than intramuscularly.

Paul Ehrlich standardized the strength of diphtheria antitoxoin and defined 1 unit as the amount of toxin needed to kill a 250-g guinea pig in 4 days.[197]

McCloskey and Smilack[446] determined the antitoxin content of standard human IG. None of the lots tested contained diphtheria antitoxin in sufficient titer to allow its use for antitoxin therapy. They suggested that an IGIV with higher titer antitoxin be developed to eliminate the

risk for giving horse serum intravenously. Indeed, such a product is produced and used in the Ukraine.[214]

Recommendations

Diphtheria antitoxin of equine origin is indicated for all suspected or proved cases of diphtheria.[22] It is available in vials containing 20,000 U from the CDC. Before administration, skin tests must be performed to determine sensitivity. If the patient has a previous history of serum reactions or these test results are positive, a schedule of desensitization as outlined earlier must be followed.

The amount of antitoxin given depends on the location and the extensiveness of the membrane, the degree of systemic toxicity, and the duration of illness. The preferred route is intravenous, although intramuscular administration has been used historically in milder cases.

In all cases, diphtheria antitoxin should be given promptly rather than be delayed while awaiting bacterial confirmation of the diagnosis.[22]

In cutaneous diphtheria, antitoxin is of uncertain value. When used, the dose is 20,000 to 40,000 U to prevent toxic sequelae. In pharyngeal or laryngeal disease, 20,000 to 40,000 U is given; in nasopharyngeal disease, 40,000 to 60,000 U is given; and in extensive disease with neck edema or disease of more than 3 days' duration, 80,000 to 120,000 U is given.[22] Although antimicrobial therapy is a valuable aid in the treatment of diphtheria, it is not a substitute for antitoxin therapy.

Routine use of antitoxin in an asymptomatic, exposed susceptible patient is not recommended. With heavy exposure or an extremely susceptible host, antitoxin 5000 to 10,000 U intramuscularly can be given in addition to antibiotics and diphtheria immunization. Proof of efficacy is lacking, however.

In 1936, Wade Hampton Frost demonstrated that diphtheria toxoid given to school children was effective in preventing disease and resultant mortality.[229] Diphtheria antitoxin is used to prevent diphtheria and is contained in the currently used diphtheria-pertussis-tetanus (DTaP) and tetanus-diphtheria (Tdap) vaccines.

Human IGIV has variable amounts of diphtheria antitoxin, so it cannot be used as a replacement for animal antitoxin.[22]

PERTUSSIS

Pertussis antiserum was used in the 1930s for the treatment of pertussis.[100] Human pertussis IG was developed in the 1960s but was shown to have no additive benefit to antibiotics in the treatment of pertussis[60,471] and no longer is available commercially.

Granström and coworkers[262] used an experimental human hyperimmune serum from subjects immunized with a two-component acellular vaccine to treat 33 children, and an equal number received an albumin placebo. Both groups received the same antibiotic and supportive treatment. The treated children had decreased coughing and whooping, particularly if treatment was started early in the course of disease. There was no significant difference in the duration of hospitalization.

Ichimaru and colleagues[314] successfully used a high-titer human IGIV preparation to treat a severely ill 1-year-old child.

Bruss and associates[116] studied a 4 percent high-titer human pertussis IG in 26 children with pertussis and found that the product was safe at three dose levels (250, 750, and 1500 mg/kg) and provided good serum pertussis IgG levels with a half-life of 38 days. High titers of anti-PT antibodies were produced, and other studies have correlated such titers with protection against disease in animal models after aerosolized challenge.[115,590] Little antibody appeared in nasal secretions. Efficacy was not evaluated in this study, but the suggestion was made that treated infants had a shorter duration of paroxysms and the product was effective in the treatment of aerosol-induced pertussis in mice.[115]

A subsequent randomized, double-blind, placebo-controlled phase 3 trial that enrolled 25 infants was terminated because of unavailability of study product and poor recruitment. Preliminary analysis did not suggest a clinical benefit in symptoms such as cough, apnea, and oxygen desaturation in contrast to placebo.[284]

Recommendation

Because of the lack of well-designed, placebo-controlled, double-blind trials of immunomodulating agents, currently no recommendation exists for the role of passive immunity for pertussis.

RESPIRATORY AND OTHER BACTERIAL INFECTIONS

Respiratory tract infections caused by group A streptococci, *S. pneumoniae*, *H. influenzae* type b, and, to a lesser extent, *Neisseria meningitidis*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae* are well recognized as occurring more frequently in patients with primary antibody deficiencies, and these infections can be reduced markedly by the regular administration of IGIV or IGIM.[219,405,499] IGIV represents a viable adjunct treatment option for certain cases of drug-resistant bacterial infections, and there is a clear survival advantage with the use of IGIV in adult sepsis syndromes by suppressing inflammation.[219] Furthermore, specific animal antisera to some of these organisms were used in the early 1930s for the treatment of severe infections (e.g., meningitis), even after the introduction of sulfonamides.[15] Efficacy varied but was clearly better than no treatment at all, and a combination of sulfonamides and antibody seemed to be synergistic.[15]

Small doses of IGIM (100 mg/kg/month) did not prevent or improve the course of respiratory infections in normal children.[69,223] However, Nydahl-Persson and colleagues[495] gave 24 children with repeated bacterial respiratory infection (i.e., pneumonia or otitis media) either trimethoprim-sulfamethoxazole or IGIV 400 mg/kg/month; both agents were effective in reducing the number of infections in comparison with a control group.

Santoshan and associates[587] administered a human intramuscular IGIM prepared from the sera of donors immunized with pneumococcal, meningococcal, and *H. influenzae* type b polysaccharide vaccines (bacterial polysaccharide IG [BPIG]) to Apache Indian infants living on reservations in Arizona. Of the 703 infants studied, 222 infants in the study group received 3 doses of BPIG, 0.5 mL/kg, at 2, 6, and 10 months of age, and the 218 infants in the control group received saline injections at the same ages. During the study period, seven cases of invasive *H. influenzae* type b disease and four cases of invasive pneumococcal disease occurred in the control group in contrast to one and two cases, respectively, in the BPIG-treated group, a significant difference ($p < .05$).

Otitis Media

Immunologically normal otitis media–prone children seem to derive little preventive or therapeutic benefit from low-dose IG given intramuscularly (100 mg/kg/month)[338] or intravenously (200 mg/kg/month).[346]

In patients with primary immunodeficiency, the frequency and severity of episodes of otitis media are diminished dramatically by the use of IG in large doses. In children with secondary antibody deficiency associated with HIV infection, IGIV in large doses (400 mg/kg/month) reduced the frequency of otitis media by 60 percent.[468,467] Patients with subtle immunologic abnormalities such as IgG subclass deficiencies, IgA deficiency, and polysaccharide antibody deficiencies may have recurrent episodes of otitis media that can be reduced with a large dose of IGIV (e.g., 400 mg/kg/month).[346,375,495,616,621]

BPIG also was shown to reduce the number of episodes of pneumococcal otitis media in high-risk Native American infants.[616] It did not, however, decrease the total number of episodes of otitis media. Large doses of RSV-IVIG (750 mg/kg/month) reduced the frequency of non-RSV otitis in young infants.[624] This product may have high antibody titers to bacteria and other viruses.[204]

Ishizaka and coworkers[321] successfully treated seven children with recurrent pneumococcal otitis media with IGIV.

The studies discussed here indicate that low-dose IGIM is ineffective in the prevention or treatment of otitis media, but high doses of IGIV (e.g., >400 mg/kg/month) may reduce the frequency and severity of otitis media in immunodeficient and otitis-prone normal children, probably by reducing both virally and bacterially mediated disease.[289] Englund and Glezen[203] suggested that passive immunization transplacentally from a recently immunized pregnant mother with *H. influenzae* or pneumococcal vaccine also should be considered.

IGIV should not be used routinely for otitis media–prone normal children but in extreme cases can be considered after failure of prophylactic antibiotics and pneumococcal immunization.

Sinusitis

Sinusitis is a common occurrence in immunodeficient patients and is difficult to prevent or eradicate, even with optimal treatment. Mofenson and colleagues[467] found that neither IGIV 400 mg/kg/month nor three times weekly sulfonamide prophylaxis prevented sinusitis from developing in children with HIV infection. Prospective data demonstrated that IGIV replacement treatment does not reduce or resolve chronic sinusitis,[219] however Desrosiers and Kilty[184] suggest IGIV may be an option in very refractory patients after endoscopic sinus surgery.

In patients with no or subtle immune defects (e.g., IgG subclass deficiencies and impaired polysaccharide antibody deficiencies), high-dose IGIV sometimes may decrease the frequency and severity of sinusitis.[104,155,549,621]

Lower Respiratory Tract Infections

Although high-dose IGIV is of proved benefit in preventing pneumonia in immunodeficient patients[122]; however, no evidence exists that it will prevent pneumonia in normal patients. Anecdotal cases of IGIV used as adjunctive therapy for refractory viral pneumonia have been reported.[579,654]

Cystic Fibrosis

Winnie and associates[742] suggested that IGIV may improve pulmonary function in pulmonary exacerbations of cystic fibrosis. All patients received antibiotics, were older than 12 years, and had no long-term benefit from the IGIV. Van Wye and coworkers[704] had similar results with the use of hyperimmune *Pseudomonas* IGIV in patients with cystic fibrosis.

A controlled trial of *Pseudomonas* hyperimmune IGIV in 116 patients with cystic fibrosis was discontinued because a 6-month interim analysis showed no reduction in acute pulmonary exacerbations.[544]

Balfour-Lynn and colleagues[62] suggested that high-dose IGIV was of short-term benefit, in both improving pulmonary function and in decreasing the need for steroids, in selected patients with cystic fibrosis and respiratory obstruction receiving inhaled and oral steroids.

In one study of 186 infants with cystic fibrosis, 92 receiving palivizumab and 94 receiving placebo over a single RSV season, the outcomes were similar between the groups and more research is required to recommend palivizumab prophylaxis in children with cystic fibrosis.[563]

Burn Infections

Kefalides and associates[359] reduced the mortality rate of severely burned children by administering plasma (1 mL/kg for each 1% of surface area burned) or IGIM (1 mL/kg on days 1, 3, and 5) from 40 to 20 percent. They concluded that solutions containing antibodies (plasma or IG) were more effective in reducing the complications of infections than were other colloids. However, Stone and colleagues[658] could not achieve any clinical benefit from IGIM therapy (0.4 mL/kg every third day until skin coverage) in 60 burned subjects versus 40 controls.

Convalescent plasma, special IG with high antibody titer to *Pseudomonas*, and *Pseudomonas* vaccines also have

been used in burn patients in an attempt to reduce infections, but without proof of efficacy.[172,188,335,482,615]

An observational study suggested that the combined use of IGIV and polymyxin B reduced the number of septic episodes and shortened the length of hospital stay in severely burned children.[428]

Firoz and colleagues[225] summarized 5 years of experience with 82 patients with toxic epidermal necrolysis in a burn unit in San Antonio and found no mortality benefit to the use of IGIV versus supportive care.

Gram-Negative Infections

The most extensive use of IG for infections in adults has involved trauma, shock, and postoperative patients thought to have gram-negative infections, as reviewed earlier under secondary immunodeficiency.* A meta-analysis involving 492 patients receiving polyclonal IGIV for sepsis and septic shock suggested a benefit, particularly among adults.[14] Monoclonal antibodies to endotoxin or cytokines were not of benefit. We conclude that this is a promising yet unproved use for IGIV.

Newborn Sepsis

As noted earlier, newborns and premature infants in particular are highly susceptible to bacterial sepsis and its sequelae. In addition to antibiotics, leukocytes, granulocyte colony-stimulating factor, and IGIV have been used as adjunctive therapy. As discussed earlier under secondary immunodeficiencies, numerous studies on the prevention and treatment of newborn sepsis are available and some suggest only slight benefit in prevention of sepsis. Ohlsson and Lacy[506] reviewed the literature regarding the use of IGIV for suspected or subsequently proved infection in neonates and found insufficient evidence exists to support the routine administration of IGIV for neonatal sepsis. In 2011, a large collaborative study of 113 hospitals in nine countries supported this conclusion. They evaluated the use of IGIV in neonatal sepsis and found no effect on the outcome of suspected or proven neonatal sepsis.[274]

IGIV may be considered for septic premature infants not responding well to conventional therapy; however, the evidence to date does not support its use. It may be particularly valuable for neutropenic septic infants because it may help mobilize leukocytes from the storage pool.

STAPHYLOCOCCAL INFECTIONS

Staphylococcal infections are ubiquitous and of varying severity. They include superficial skin infections, acute infections such as abscesses and wound infections, deep-seated indolent cellulitis, and three toxin-mediated diseases: scalded skin syndrome, toxic shock, and acute food poisoning. Antibiotics usually are effective in controlling the infections, but in some instances, the organism is antibiotic resistant or the disease is rapidly progressive. IGIV may be of adjunctive benefit in some of these situations.[362,716]

In addition to the use of IGIV, novel antistaphylococcal antibodies are being developed and are currently in clinical trials. Antibody products are directed against a variety of targets on the staphylococcal organism (i.e., capsule, lipoteichoic acid, and toxins). These products are in phase I and II trials. These antibodies are being developed for both prevention and treatment of staphylococcal disease.[504]

Altastaph is an example of a hyperimmune polyclonal IG preparation that targets CP5 and CP8 capsular polysaccharides. It was shown to prevent *S. aureus* bacteremia in mice but two phase II clinical trials failed to demonstrate efficacy.[76,233,575]

Staphylococcal Toxic Shock Syndrome

Patients with staphylococcal toxic shock syndrome, often associated with tampon use by menstruating women, have a rapid onset of fever, shock, macular desquamating rash, and multisystem organ failure.[37,458,607] The pathogenesis of the disorder results from infection with a strain that releases toxic shock syndrome toxin (TSST-1).[37] Approximately 20 percent of all staphylococcal isolates carry the gene for this toxin.[419] TSST-1 is a potent superantigen that directly activates the 5 percent of T cells that have a Vβ2 T-cell receptor[419]; such activation results in the rapid release of multiple cytokines and a clinical picture of rapidly progressive illness. Recent reports have implicated methicillin-resistant *S. aureus* (MRSA) in severe toxic shock syndrome.[327]

IGIV contains neutralizing antitoxins to the staphylococcal (and streptococcal) superantigens[674] and has been used successfully in both animal models of toxic shock syndrome[37] and several patients.[501,524,595] Although no controlled clinical trials have been performed for staphylococcal toxic shock syndrome, most authorities recommend large IGIV doses, at least 400 mg/kg, in addition to antibiotic treatment and circulatory support.[37] IGIV also downregulates cytokine synthesis and action and inhibits immune activation, thereby providing additional benefits.[37]

Higuchi and coauthors[301] reported a large family that had recurrent episodes of staphylococcal toxic shock syndrome associated with normal IG levels but low serum antibody titers to staphylococcal superantigens; two boys in the family achieved successful prophylaxis with regular IGIV infusions.

Neonatal Staphylococcal Infections

A second situation in which the administration of passive immunity may be of value is neonatal staphylococcal infection. Infection with *S. epidermidis*, is the most common cause of sepsis in premature infants and is aggravated in part by the use of catheters and parenteral lipid infusions.[57,226] Infections with *S. aureus* are also problems in neonatal intensive care units. Use of passive immunity directed at reducing *S. aureus* infections has been tested.

*References 72, 125, 180, 219, 251, 341, 764, 765.

One controlled study showed that IGIV was of value in decreasing the incidence of infections but not eliminating them,[57] but this benefit has not been found in all trials of IGIV in newborns. Although the administration of IGIV increased IgG levels in newborns, the overall morbidity and death as a result of nosocomially acquired sepsis were unchanged.

This variability may be explained by differing amounts of staphylococcal antibodies present in different IGIV brands and lots, particularly opsonic antibodies, which have been shown in animal models to be the most important correlate of clinical protection.[226] Because antibody variability exists in lots of IGIV made from pools of thousands of donors, it is not surprising that Krediet and colleagues[383] could not reliably increase the opsonic titers of premature infants by administering single-donor fresh-frozen plasma. Given that pooled IGIV has not been shown to decrease mortality in this high-risk population, the development of organism-specific IG has been explored. INH-A21 (Veronate) is a plasma-derived, donor-selected polyclonal antistaphylococcal human IG. A phase II, multicenter, double-blind clinical trial of this antibody was conducted on 512 low-birth-weight infants (50 to 1250 g), but no clinically significant differences were seen in the incidence of either *S. aureus* or coagulase-negative staphylococcus (CoNS).[88]

In a recent phase III trial with a larger enrollment, 1983 infants received either placebo or the study drug (INH-A21). The investigators were unable to demonstrate benefit in protection against late-onset sepsis resulting from either *S. aureus* or CoNS. The incidence of sepsis in the placebo group was 5 percent, in contrast to 6 percent in the treatment group.[181]

Pagibaximab, a humanized mouse chimeric monoclonal antibody directed against lipoeichoic acid, a cell wall component of gram-positive bacteria, is currently in development for prevention of gram-positive infections. A phase I and II double-blind, placebo-controlled, dose-excaltion, safety and pharmacokinetic study in infants with very low birth weight demonstrated safety and tolerability.[728] A follow-up phase II multicenter study of 2- to 5-day-old neonates, weighing 700 to 1300 g, demonstrated safety and at a dose of 90 mg/kg produced potentially protective antibody levels (>500 μg/mL).[729]

Severe Staphylococcal Infections

The last decade has seen an emergence of highly virulent and antibiotic-resistant strains of *S. aureus*. These strains are responsible for aggressive infections, including necrotizing fasciitis, and pulmonary necrosis. The virulence factors are currently being elucidated, and the Panton Valentine Leukocidin *(pvl)* gene product has been correlated with higher morbidity and mortality in MRSA infections[90] The precise role that *pvl* plays in the pathogenesis of severe *S. aureus* infections is unclear; however, it may provide a target for antibody neutralization in a severe toxin-mediated disease process.[108] Children with PVL-positive MRSA infections have been shown to mount a robust antibody response to PVL, but this antibody does not seem to be protective against future infections with the same organism.[299]

Neutralization of *S. aureus* PVL by IGIV in vitro has been demonstrated and shown to neutralize pore formation and the cytopathic effect of *S. aureus*.[236] Given this in vitro data, as well as the use in other diseases with toxin production such as toxic shock syndrome, the use of IGIV in aggressive infections caused by PVL-producing *S. aureus* could be considered as adjuvant therapy along with early débridment and active antimicrobial therapy.[288,753]

Refractory Staphylococcal Infections

A final use of IG is for the treatment of antibiotic-resistant chronic staphylococcal infection, along with intravenous antibiotics. Waisbren[716] treated 16 such patients with an antibiotic and gammaglobulin combination, with recovery noted in 13 of them. Indeed, hyperimmune plasma and IG from patients immunized with staphylococcal toxoids are widely used in Russia with apparent success.[362]

Recommendations

Large doses of IGIV are indicated for the treatment of staphylococcal toxic shock syndrome.[36] The recommended regimen is a single dose of 1 to 2 g/kg or 400 mg/kg daily for 5 days. A repeated dose may be necessary because of rapid clearance of IGIV in this illness.[36]

The value of IGIV in refractory chronic staphylococcal infections is unproven, although anecdotal reports of efficacy exist.[716]

IGIV is not recommended routinely for the prevention of infection in premature newborn infants. As noted earlier, IGIV may be of adjunctive benefit in the treatment of neonates with sepsis, particularly those with neutropenia.[330] Development of specific antistaphylococcal IGs to prevent staphylococcal infection in infants with very low birth weight continues to be an active area of investigation.[604]

STREPTOCOCCAL INFECTIONS

Circulating antibody may play a role in the prevention and treatment of group A streptococcal infection.[348] Newborns rarely develop invasive streptococcal illness, in part because of protective transplacental antibodies.[348] Equine antitoxin was used with some success in the treatment of erysipelas and scarlet fever in the 1920s and 1930s.[422,666]

Invasive Group A Infections

Invasive group A streptococcal infections, including septicemia, necrotizing fasciitis or myositis, and toxic shock syndrome, are of increasing severity and frequency.[23] Streptococcal pyrogenic exotoxins, including types A, B, and C, and mitogenic factor elaborated by certain strains of streptococci may be responsible for these serious complications of infection. Streptococcal pyrogenic exotoxins

are potent superantigens that activate certain T lymphocytes directly and lead to the massive production of multiple cytokines, with resultant shock, fever, and organ failure. IGIV contains neutralizing antibodies to these antigens,[492,493] but at varying titers across batches.[597]

Invasive soft tissue infections with group A streptococcus may benefit from high-dose IGIV.[174,249,492] In contrast to these reports, Mehta and colleagues[456] could not document a benefit for IGIV in patients admitted to the ICU with invasive group A infections from any cause.

Streptococcal Toxic Shock Syndrome

Many case reports have attested to the value of IGIV in streptococcal toxic shock syndrome since the report by Barry and coauthors in 1992.[13,70,177,402,535]

Kaul and colleagues[354] reported a study of 21 consecutive patients at several Canadian medical centers in 1994 and 1995 treated with IGIV and compared them with 32 similar patients not given IGIV at the same centers for the 3 preceding years. Both groups received appropriate antibiotics and were similar with regard to demographics, severity score, and timing of intervention. The median IGIV dose was 2 g/kg. The survival rate for the IGIV-treated group was significantly greater at 7 and 30 days (90% and 67%, respectively) than that in the untreated controls (50% and 34%, respectively; $p = .02$), and the days of hospitalization were insignificantly shortened (29 vs. 39). Serum from the IGIV-treated patients caused a marked inhibition of lymphocyte mitogenic activity to their own bacterial isolates after a single IGIV dose. This study excluded children from the analysis because of ethical considerations and the overall lower mortality seen in younger age groups.

In a large multicenter retrospective trial of children with streptococcal toxic shock syndrome[605] IGIV was administered to 84 of 192 children with streptococcal TSS and overall mortality, as well as overall hospital and drug costs, were evaluated. The investigators found no added benefit of IGIV infusion and noted the increased costs of IGIV administration.

PANDAS Syndrome and Sydenham Chorea

Murphy and colleagues[476] and Swedo and coauthors[665] reported a syndrome of tics, obsessive-compulsive behavior, or both, occurring in prepubertal children soon after the onset of a streptococcal infection. They termed this disorder *pediatric autoimmune neuropsychiatric disorder associated with streptococcal disease syndrome* (PANDAS syndrome). They reported suggestive benefit of IGIV.[536]

Treatment of Sydenham chorea, a movement disorder following streptococcal infection, with IGIV has also been anecdotally reported.[702]

The National Institute of Mental Health has an ongoing trial examining the benefits of patients with PANDAS with IGIV.*

*National Institutes of Health PANDAS clinical trial: http://clinicaltrials.gov/ct2/show/NCT01281969.

Recommendations

The use of IGIV can be considered as adjunctive therapy of toxic shock syndrome or necrotizing fasciitis in severely ill patients. Various regimens of IGIV, including 150 to 400 mg/kg/day for 5 days or a single dose of 1 to 2 g/kg, have been used, but the optimal regimen is unknown.[23] Repeated administration of IGIV may be necessary after a few days because of rapid IGIV catabolism.

IGIV may be of benefit in severe streptococcal soft tissue infections such as necrotizing fasciitis. IGIV is of unproved benefit in PANDAS syndrome.[511]

TETANUS, TETANUS ANTITOXIN, AND TETANUS IMMUNOGLOBULIN

Antitoxin for the treatment of tetanus was introduced into medicine by Behring and Kitasato in 1890; large doses (50 to 100 mL) of serum from horses immunized with tetanus toxin were used. The dose was increased gradually to 300 to 500 mL, equivalent to 300 to 500 U of antitoxin. As the means to increase the production and concentration of antitoxin developed and a high mortality rate persisted, the dosage of antitoxin was increased until doses as high as 200,000 U, repeated at weekly intervals, were recommended.[531] Despite such heroic therapy, no solid proof of efficacy was obtained.

However, in 1960, Brown and colleagues,[107] using sequential analysis, found that the mortality rate was 49 percent in 41 patients with tetanus who received 200,000 U of antitoxin, a statistically significant difference that established therapeutic efficacy. Extensive controlled studies established that mortality rates did not improve when larger doses (100,000 to 500,000 U) were used.[421,695-697]

Similarly, Patel and associates[529] could find no difference in the mortality rates of patients with tetanus treated with antitoxin doses of 5000 to 60,000 U. Adequate blood levels of antitoxin were noted in all cases, even in fatal cases, with a dose of 10,000 U. In mild cases, no antitoxin was necessary. They and others have reported considerable differences in mortality rates, ranging from 0 to 98 percent; the rate depends primarily on the severity of illness rather than on the dose of antitoxin.

Athavale and colleagues[53] established that antitoxin was of benefit in tetanus neonatorum and in tetanus in children up to 12 years of age. Antitoxin affected the mortality rate in mild and moderate cases but not in severe ones. A dose of 10,000 U was as effective as one of 30,000 U.

The mechanism of action of antitoxin is to neutralize toxin before it is transported to the nervous system through the circulation. Antitoxin also can neutralize toxin locally and prevent its systemic absorption. Thus, antitoxin can be given locally, at the site of production of toxin (e.g., at the site of a wound), intravenously (in severe cases), or intramuscularly (in less severe cases).

In 1962, an estimated 750,000 annual doses of equine tetanus antitoxin were needed in the United Kingdom,

which is equivalent to more than a million doses in the United States.[573] Serum sickness occurs in 6 to 14 percent and fatal anaphylaxis in 1/100,000 injections of equine-derived antitoxin. Thus, hyperimmune human tetanus IG (TIG), first available in the early 1960s, gradually has replaced equine tetanus antitoxin.

Rubbo and Suri[572] and Rubinstein[573] showed that TIG given intramuscularly (5 to 10 U/kg) provides adequate circulating antitoxin levels and is maintained in the circulation for considerably longer than is equine tetanus antitoxin.

The efficacy of TIG is equivalent to that of equine tetanus antitoxin. McCracken and associates[448] compared the results of 550 U of TIG with 10,000 U of tetanus antitoxin in the treatment of tetanus neonatorum. Among the 65 infants in each treatment group, no difference was noted in severity, length of hospitalization, need for sedation or gavage feeding, or mortality rate. Blake and colleagues[85] analyzed 545 tetanus cases reported to the CDC from 1965 to 1971 and found no difference in the outcome of patients treated with equine tetanus antitoxin versus TIG.

The first use of intrathecal antitoxin was recorded in 1898 by Charles Church and Dr. Rambord from the Pasteur Institute and by Cushing in 1899.[531] In 1902, a French surgeon reviewed 27 cases of tetanus treated with intrathecal antitoxin and concluded that there was no additional benefit.[739]

Gupta and associates[280] gave TIG intrathecally to alternate patients with early tetanus. Among 49 patients given intrathecal TIG (250 U), 3 deteriorated and 1 died; among 48 patients given intramuscular TIG (1000 U), 15 deteriorated and 10 died. No side effects occurred. Herrero and coworkers[300] could not prove a benefit of administering intrathecal antitoxin for tetanus neonatorum. Although an early meta-analysis of intrathecal therapy cast doubt on its efficacy,[5] studies from India[238] and Brazil[462] and a larger meta-analysis[342] suggested beneficial effect of intrathecal antibody.

TIG can be given along with tetanus toxoid for passive–active immunization. A dose of 250 U of TIG given intramuscularly at a site different from that of the toxoid does not interfere with the active antibody response.[447]

Lee and Lederman[404] measured the tetanus antitoxin titers in 29 lots of IGIV and noted considerable variability, although all lots had titers greater than 4 U/mL (mean, 21 U/mL). All lots would provide sufficient anti–tetanus toxin antibody if used at doses of 100 mg/kg as an alternative to TIG or tetanus antitoxin.

Recommendations

Prophylaxis

If a nonimmunized person sustains a serious injury or a bite, 250 to 500 U of TIG should be given intramuscularly as soon as possible.[35] The larger dose is used in the event of an extensive wound or delay in treatment. TIG is available for intramuscular administration in individual vials containing 250 U. Alum-precipitated toxoid to initiate active immunity is given at a different site with a separate syringe.

Human IGIV also can be used if TIG is not available and should be administered at a dose of 200 to 400 mg/kg.[35] This use of IGIV is not FDA approved and the antitetanus antibody levels in IGIV are not routinely assessed.

If TIG or IGIV is unavailable, tetanus antitoxin (equine) can be administered (after screening and testing for serum sensitivity have been performed).[35] Equine antitoxin for human use is available in several countries, but not in the United States, where TIG is available.

Treatment

In addition to administration of antibiotics and management of the wound, TIG should be given, but the optimal dose has not been established. At least 500 U is recommended, but doses as high as 3000 to 6000 U have been used. Part of the TIG is infiltrated near the wound, and the remainder is administered intramuscularly.[35] If the wound is extensive, TIG can be diluted with saline to infiltrate the entire area. TIG also is indicated for the treatment of tetanus neonatorum. Recent meta-analyses suggest that intrathecal use is of benefit in both adults and infants.[342] A study of infants with neonatal tetanus showed mild improvement in outcome in infants who received intrathecal TIG.[11]

Equine tetanus antitoxin has been used when TIG is unavailable, however this product is not available in the United States. If given it should be given in a single dose of 100,000 U, with 50,000 U given intramuscularly and 50,000 intravenously (after appropriate testing for sensitivity). On recovery, the patient should undergo primary immunization.

In tetanus neonatorum, McCracken and associates[448] found that 500 U of TIG given intramuscularly and 10,000 U of equine antitoxin were equally efficacious. Intrathecal TIG has been recommended[280,342,453] but is not always of benefit.[75,300] However, TIG is not licensed for this use.

PASSIVE IMMUNITY IN VIRAL INFECTION

ENTEROVIRUSES

Poliovirus

Before the development of poliomyelitis vaccines in the mid-1950s, IGIM was used extensively for the prevention of poliomyelitis. Bodian[91,92] showed that Red Cross IGIM had neutralizing antibody to all three strains of poliovirus in approximately equal titer and that rhesus monkeys given intramuscular poliovirus could be protected against disease by the subcutaneous administration of IGIM.

Bloxsom,[89] in an uncontrolled study performed during a 1948 Texas epidemic, gave 841 contacts an average dose of 2 mL of IGIM and noted only four cases at 1, 2, 3,

and 42 days after administration of the IGIM injection. His interpretation was that IGIM had been given too late to prevent the first three cases and that protection had worn off in the fourth case.

A committee on immunization of the National Foundation for Infantile Paralysis recommended in March 1951 that a controlled study be conducted on the efficacy of IGIM for the prevention of poliomyelitis during epidemics. Hammon and associates[287] subsequently undertook a massive field study in communities in three states during poliomyelitis epidemics.

Fifty-five thousand children aged 1 to 11 years received either IGIM (average dose, 0.14 mL/lb) or gelatin in a double-blind fashion. During the first week after injection was administered, 12 cases occurred in the IGIM recipients and 16 cases in the gelatin recipients. In the two groups, 3 and 23 cases occurred in the second week and 6 and 38 cases occurred in the third to fifth weeks, respectively. When protection was incomplete, decreased severity was noted. Protection waned by 6 weeks and disappeared by 8 weeks. These clinical results were confirmed by isolation of the virus or a rise in antibody titer in affected patients.

IGIM was an inefficient method of poliomyelitis prophylaxis in that it prevented only one case for every 500 to 2000 injections, and only for a brief time. Its chief value was in close family contacts of affected children and in aborting severe local epidemics.

Recommendations

The use of IGIM rarely is indicated for the prevention of poliomyelitis. An exposed unimmunized subject can be given 0.31 mg/kg of IGIM. An unimmunized patient who is traveling to an endemic or epidemic area and who cannot have vaccine can be given this dose of IGIM for temporary protection.

An immunodeficient patient inadvertently exposed to live attenuated polio vaccine who is excreting poliovirus in stool may be a candidate for receiving IGIV and oral IG in an effort to rid the gastrointestinal tract of the virus.

Other Enteroviruses

Enteroviruses, particularly echoviruses and coxsackieviruses, can cause severe disease in neonates[320,414] and in immunodeficient patients, particularly those with X-linked agammaglobulinemia or common variable immunodeficiency.[559] IGIM and IGIV have been used in both groups for the prevention and treatment of these infections.[559]

Meningoencephalitis

Chronic enteroviral meningoencephalitis with severe neurologic findings may develop in agammaglobulinemic patients; however, the incidence has decreased since routine treatment with IGIV has been instituted for these patients. IGIV does not prevent all cases, likely as a result of differing titers of antibodies to different enteroviral serotypes. McKinney and coworkers[451] summarized the results of treatment of 42 patients with chronic enterovirus meningoencephalitis: 10 received IGIM or plasma (1 survived), 10 received IGIV (7 survived), and 12 received both intraventricular IGIV and systemic IGIV (10 survived).

Misbah and colleagues[463] reviewed 15 patients with chronic enteroviral meningoencephalitis not included in the McKinney report, some of whom, however, had been described by others.[194,380] Of the 5 patients treated with IGIV, 3 survived, and of 10 treated with IGIV and intraventricular or intrathecal IGIV, 5 survived. Mellouli and colleagues[459] successfully treated an agammaglobulinemic boy who developed echovirus meningoencephalitis while receiving IGIV with intraventricular IG through an Omaya reservoir in addition to aggressive intravenous therapy.

Quartier and associates[547] reported complete clinical and virologic remission in 2 patients with X-linked agammaglobulinemia, as determined by both culture and polymerase chain reaction (PCR) assay. The first patient was treated with IGIV and a brief course of pleconaril. The second patient was treated with IGIV and pleconaril, but intraventricular IG was added when CSF pleocytosis persisted after 11 months of therapy. Complete clinical and virologic remission persisted at the 20-month follow-up. This study indicated that CSF PCR assay can be used, in addition to viral culture, as a guide to successful therapy.

Neonatal Enteroviral Infection

Severe and sometimes fatal disseminated enterovirus infection can develop in neonates.[548] Case reports have suggested benefit with the use of IGIV.[320,334,699] Kimura and coworkers[370] treated coxsackievirus B3 infection in four term infants with IGIV. The three who were treated early survived, but the infant treated 6 days after the onset of infection died. Abzug and associates[6] treated nine infants with echovirus and coxsackievirus B infection with IGIV but without apparent benefit; however, three of five infants who received high-titer IGIV had a shortened period of viremia. Rentz and colleagues[560] suggested that the maternal plasma might be used in lieu of IGIV as a source of high-titer antibody in newborns with a severe enteroviral infection. In summary, IGIV is of uncertain value, particularly if its titer against the particular virus is not known.

Nagington and colleagues[477] used IGIM successfully in an echovirus 11 outbreak in a special care nursery, but Kinney and coworkers[371] could not demonstrate a benefit of using IGIM in a similar nursery with the same virus. Pasic and associates[528] administered IGIV at 400 mg/kg prophylactically during a nursery echovirus 6 outbreak and thought that the severity of illness was decreased, although viral transmission continued.

Recommendations

IGIV may be used for critically ill neonates with disseminated enterovirus infection, although its benefit is unproved. In an outbreak situation with a known serotype and the availability of IGIV with significant titer to this serotype, IGIV should be considered.[678] Multiple

doses of 500 mg/kg as well as single doses of 750 to 1000 mg/kg have been used.[6,334,370,699]

For chronic enteroviral meningoencephalitis, McKinney and colleagues[451] recommend that sufficient IGIV be administered to maintain an IgG serum trough level of 900 to 1000 mg/dL. Even higher doses may be needed if the IGIV titer for the infecting virus is low. Quartier and coworkers[547] used 500 mg/kg of IGIV every 24 to 48 hours for 2 weeks, followed by 500 mg/kg two to three times per week for 6 weeks and then gradual reductions, but with maintenance of the trough IgG level at greater than 800 mg/dL.

Administration of IGIV by intraventricular catheter should be considered for patients who do not improve despite receiving aggressive therapy with IGIV. IGIV for intraventricular administration should have a neutral pH, be given slowly, and be at room temperature.[451] Dwyer and Erlendsson[194] used 6 percent IGIV intraventricularly, starting at doses of 120 mg/day and increasing to 600 mg/day during the first week of treatment, followed by doses of 300 mg/day for 1 to 4 weeks. Quartier and colleagues[547] administered 300 mg of IGIV daily for 15 days and then 300 mg three times per week to a patient whose intravenous IGIV therapy had failed. The duration and frequency of both intraventricular and intravenous IGIV must be individualized and determined by clinical and virologic response and normalization of CSF and ventricular fluid. An IGIV with a high titer to the infecting serotype should be used for both systemic and intraventricular therapy.

HEPATITIS A

The widest use for human IGIM has been for the prevention of hepatitis A, but this indication has been decreased by the widespread use of hepatitis A vaccine.[24] The efficacy of IGIM was demonstrated in 1945 by Stokes and Neefe[656] in aborting an epidemic in a children's summer camp, by Havens and Paul[292] in controlling an institutional epidemic, and by Gellis and associates[239] in preventing hepatitis A in the Mediterranean theater of operations at the close of World War II. The administration of combined IGIM and hepatitis A vaccine and scrupulous cleanliness can be used to interrupt the intestinal–oral circuit of transmission to abort an incipient epidemic.

IGIM is efficacious in preventing hepatitis A if it is given within 2 weeks of the last exposure.[9,24] Protection typically persists for 6 to 8 weeks. Stokes and associates[655] note that a single dose of IGIM (0.02 mL/kg) provided a degree of protection for up to 9 months in individuals residing at an institution in which hepatitis A was endemic.

The effectiveness of IGIM in hepatitis A varies from 80 to 95 percent, depending on how soon it is administered after exposure and the severity of the exposure.[721] IGIM suppresses clinical manifestations of the disease, but anicteric hepatitis is not prevented and the ratio of anicteric to icteric hepatitis may be as high as 12 : 1.[390] The period of protection exceeds the expected duration of the IGIM, supporting the concept of passive–active immunity; the hypothesis is that as a result of continuous exposure, a mild illness ensues and in turn confers long-lasting immunity.[390,653,719]

In initial studies, Stokes and Neefe[654] used an IGIM dose of 0.15 mL/lb, whereas others used doses of 0.06 to 0.12 mL/lb.[241,292] In 1951 Stokes and associates[655] showed that doses as low as 0.01 mL/lb were effective in limiting spread but did not completely prevent hepatitis. Hsia and colleagues[310] in 1954 also noted that a dose of 0.01 mL/lb was effective in preventing hepatitis among family contacts. However, Ward and associates,[722] in 1958, were able to reduce the case incidence of hepatitis in institutionalized patients from 19.5 to 7.4/1000 with 0.01 mL/lb and 1.7/1000 with 0.06 mL/lb. The larger dose may be particularly important in adults because they are subject to more severe disease.

The use of serologic tests for hepatitis A provides a way to determine the immunity of a subject, the presence of inapparent infection, the titer of hepatitis A virus (HAV) in lots of IGIM, and the validity of the passive–active immunity concept.[655,656] In other earlier studies, Krugman[385] showed that an IGIM preparation with a titer of 1 : 3200 was effective in neutralizing the infectivity of MS-1 serum, a substance known to contain HAV. Farcet and colleagues evaluated the HAV antibody titer in plasma pools from March 2003 through September 2008 and determined the HAV titers adequate for HAV protection for those receiving antibody replacement for primary immune deficiency.[211]

Most current lots of IGIM have anti-HAV antibodies when they are assayed by a competitive-inhibition radioimmunoassay. Titers greater than 1 : 100 are protective.[629]

Recommendations

Household and Sexual Contacts

All previously unimmunized people with close personal contact to a person with HAV should be given a single IGIM dose of 0.02 mL/kg or single-antigen hepatitis A vaccine as soon as possible after being exposed.[9,24,708] For healthy persons aged 12 months to 40 years of age, single-antigen hepatitis A vaccine at the age-appropriate dose is preferred. For persons older than 40 years, those younger than 12 months, immunocompromised persons, persons who have had chronic liver disease, and persons for whom vaccine is contraindicated, IGIM is preferred.[488] Serologic testing for hepatitis A is unnecessary and may delay the administration of IGIM. The use of IGIM longer than 2 weeks after exposure has occurred is not indicated.[24,224]

School Exposure

IGIM usually is not necessary for children and their teachers exposed to a single case of hepatitis A in the classroom of a day school. However, if several children are infected or if transmission in the school is documented, IGIM (0.02 mL/kg) or vaccination is indicated for those unimmunized students and teachers who have close contact with the index case. IGIM prophylaxis is

recommended for children and staff exposed at a boarding school or in a school for developmentally disabled children, where opportunities for transmission by the fecal-oral route are increased.

Institutional Outbreaks

Hepatitis A outbreaks in institutions such as boarding schools, daycare centers, custodial care centers, and prisons require aggressive action; however, the frequency of these outbreaks have decreased with increasing vaccination rates. Vaccine or IGIM should be administered to all previously unimmunized staff members and attendees if one or more cases of hepatitis A are recognized in children or staff or two or more cases among households with attendees at the centers. Vaccine or IGIM should be given to all household members with persons in diapers at the centers if two or more families are affected.[9,24] If an outbreak of hepatitis A is traced to a food handler, IGIM or vaccine should be given to close contacts and other restaurant employees.[131]

Hospital and Clinic Exposure

When an outbreak occurs, vaccine or IGIM is recommended for people in close contact with the infected patient.[9]

Common-Source Exposure

Common source exposure cases generally are identified too long after the exposure occurs for IGIM to be effective. If a person has been exposed within the previous 2 weeks, IGIM or vaccine can be given (0.02 mL/kg).[9]

Community Outbreaks

Unless a source of the infection is identified, mass use of IGIM is ineffective and not recommended because it will not interfere with transmission.[52] Immunization is recommended.

Foreign Travel

Individuals going to developing countries should receive vaccine 1 month before departure. Travelers who are administered vaccine can be assumed to be protected within 4 weeks after receiving the first vaccine dose.[146,224] If the departure date is less than 2 weeks away, 0.02 mL/kg of IGIM and vaccine can be used.[24] The IGIM will provide immediate protection and not interfere with efficacy of the vaccine. If exposure to hepatitis A will continue beyond 3 months, the IGIM dose should be 0.06 mL/kg and repeated every 5 months if exposure to hepatitis A continues and the patient cannot be immunized.[9]

Primate Exposure

Certain subhuman primates such as chimpanzees may carry HAV. Animal handlers should observe scrupulous hygiene and be given hepatitis A vaccine. If bitten and unimmunized, they should receive 0.02 mL/kg of IGIM and vaccine.[146]

Needle Exposure

IGIM is indicated for susceptible persons accidentally inoculated with blood or serum from a patient with hepatitis A. The recommended dose is 0.02 mL/kg; pregnancy is not a contraindication to the administration of IGIM.

Newborn Infants of Infected Mothers

Perinatal transmission of HAV is rare. If the mother becomes symptomatic with acute hepatitis A between 2 weeks before and 1 week after delivery, the infant can be given 0.02 mL/kg of IGIM. Efficacy has not been established.[146]

HEPATITIS B AND HEPATITIS B IMMUNOGLOBULIN

Hepatitis B virus causes a wide spectrum of illness ranging from asymptomatic seroconversion to fulminant hepatitis. Although most healthy patients recover completely, the carrier state occurs commonly in exposed immunocompromised patients, such as newborns, patients taking immunosuppressive medications, and patients with primary or secondary immunodeficiencies.

Transmission occurs after exposure to blood or other body fluids, through inoculation or sexual contact, and by close personal contact such as may occur in daycare centers. The main route of transmission used to be by blood transfusion, but with donor testing, this route is no longer common in developed countries. An important route of transmission is perinatally from the mother to the newborn infant, who is likely to remain chronically infected for a lifetime. This route usually can be prevented by active and passive immunization.

Immune Globulin Use in Hepatitis B

The initial study of IGIM in hepatitis B was conducted in 1945 by Grossman and associates,[273] who treated alternate battle casualties given whole blood or plasma with two 10-mL injections of IGIM 1 month apart. The incidence of icteric hepatitis was 1.3 percent in 384 IGIM-treated patients and 9.9 percent in 384 control patients, a highly significant difference that suggested a beneficial effect of IGIM.

In 1947, Duncan and associates[192] reported the results from a similar study, although they gave only one 10-mL injection; hepatitis occurred in 1.2 percent of 2406 patients in the IGIM-treated group and in 0.9 percent of patients in the control group, an insignificant difference. However, the mean incubation period was significantly prolonged in the IGIM-treated group (to 103 days) in contrast to the control group (87 days).

Holland and associates[305] could not alter the incidence or severity of posttransfusion hepatitis in 84 open heart surgery patients given two 10-mL doses of IGIM 1

month apart in contrast to 83 non–IGIM-treated controls. These findings were confirmed in a large cooperative study of 5189 transfused cardiovascular patients given 10 mL of IGIM during the first, fourth, and seventh postoperative weeks.[258] Redeker and associates[556] could not demonstrate that IGIM protected spouses of individuals with type B hepatitis. Similarly, Kuhns and colleagues[392] could not reduce the incidence of posttransfusion hepatitis B with 20 mL of IGIM. Both of these latter studies used IGIM with low titers of antibody to hepatitis B surface antigen (anti-HBs).

Several factors probably are responsible for the variation in effectiveness of IGIM in hepatitis B. One is the variable degree of exposure to hepatitis B virus, which can be massive (as with a blood transfusion) or minimal (e.g., a household contact). A second factor is the variable levels of anti-HBs antibody in different lots of IGIM. Because IGIM does not always contain high titers of anti-HBs, it is not recommended for hepatitis B prophylaxis. Standard IG is not effective for postexposure prophylaxis against HBV infection because the concentration of anti-HBs are too low.[26]

Hepatitis B Immunoglobulin

Soon after hepatitis B surface antigen (HBsAg) and its antibody (anti-HBs) were identified, researchers could measure and select lots (or donors) with high titers of anti-HBs of at least 1:100,000 by radioimmunoassay. This product, hepatitis B IG (HBIG), has been licensed since 1978 for prevention of hepatitis B.[24,137,139]

In 1971, Krugman and associates[386,387,390] evaluated high-titer HBIG in institutionalized children injected with the infective serum MS-2. Hepatitis developed in all 11 children exposed to MS-2 serum, and 5 remained HBsAg carriers after 320 days. Among 5 children given MS-2 serum and standard IG, hepatitis developed in 3, but none became a carrier. Of 10 children exposed to MS-2 serum and HBIG, 6 were completely protected, 1 had a transient infection, and 3 developed classic hepatitis. They concluded that HBIG was 70 percent effective under these circumstances. Their later studies confirmed that HBIG could reduce the incidence, severity, and carrier rate of HBsAg significantly after prenatal exposure to hepatitis B virus.[388]

Szmuness and associates[667] tested the efficacy of HBIG versus IGIM by giving either standard IGIM or HBIG to institutionalized children at admission and at 4-month intervals for 1.5 to 2 years and compared the incidence of hepatitis with that in untreated patients. Both globulin-treated groups had a lower attack rate (11% vs. 25% in the untreated patients) and a lower incidence of persistent hepatitis B antigen (none in the globulin-treated group vs. 13.5% in the untreated group). Thus, both IGIM and HBIG were effective in preventing or modifying nonparenterally transmitted hepatitis B in an endemic setting. Anti-HBs developed in 55 percent of the patients treated with standard IGIM, whereas antibody developed in only 23 percent of the patients treated with HBIG, thus suggesting that passive–active immunity occurred more frequently in the group who received standard IGIM than in the group who received HBIG.

Seeff and associates[599] gave either HBIG or standard IGIM to 302 individuals definitively exposed orally or parenterally to material that was infectious for hepatitis B. The incidence of both clinical and subclinical hepatitis during the first 6 months was 0.7 percent in the HBIG-treated group and 6.1 percent in the IGIM-treated group. At 6 months, 32 percent of the IGIM recipients and 6 percent of the HBIG recipients had antibody, a finding indicative of minimal passive–active immunity in the HBIG-treated group.

Grady[259] reported similar results with HBIG after accidental exposure. The incidence of hepatitis at 6 months was 7 percent (of 251 patients) with standard IGIM, 5 percent (of 208 patients) with intermediate-titer HBIG, and 2 percent (of 253 patients) with high-titer HBIG. This protection waned after 6 months, and differences in the groups became less apparent after 9 months, possibly because of reexposure, delayed onset of infection, or failure of passive–active immunity

Prevention of Vertical Transmission

Beasley and associates[73,74] studied the efficacy of HBIG in preventing perinatal transmission of the hepatitis B virus carrier state from a mother to her newborn infant. HBIG or placebo was given at birth to the infants of hepatitis B early antigen (HBeAg)-positive, HBsAg-positive carrier mothers, and the infants were monitored for at least 15 months. Of 61 placebo recipients, 92 percent became carriers; of 67 infants who received 1 mL of HBIG at birth, 54 percent became carriers; and of 57 infants who received 0.5 mL of HBIG at birth and at 3 and 6 months, 26 percent became carriers. Passive–active immunization, indicated by the presence of anti-HBs, occurred in 27 percent of the single-dose group and in 61 percent in the three-dose group.

On the basis of these and other studies[332,559] suggesting that multiple HBIG doses were more effective in interrupting vertical transmission of the HBsAg carrier state than a single HBIG dose, advisory committees in the early 1980s recommended that all infants of HBsAg-positive mothers be given HBIG (0.5 mL) immediately after birth and again at 3 and 6 months.[137,139] However, many of these infants became infected sometime after their last HBIG dose (i.e., in the second or third year of life), thus indicating a need for more durable active immunity. Shi and colleagues[611] systematically reviewed the effect of HBIG given in pregnancy to interrupt mother-to-child transmission of hepatitis B. They evaluated 37 randomized control trials between January 1990 to December 2008 and concluded that there may be some benefit in HBIG use in pregnancy to prevent intrauterine transmission.

Wong and associates[748] studied the efficacy of hepatitis B vaccine given in conjunction with HBIG in the prevention of vertical transmission of the carrier state from mother to infant. They gave hepatitis B vaccine (36 infants), hepatitis B vaccine plus one dose of HBIG (35 infants), hepatitis B vaccine plus seven monthly HBIG doses (35 infants), or placebo (35 infants) to infants of HBsAg-positive mothers. In all vaccine groups, development of a persistent carrier state was reduced significantly

in contrast to the placebo group (21% with hepatitis B vaccine alone, 2.9% with hepatitis B vaccine plus one dose of HBIG, and 6.8% with hepatitis B vaccine plus seven doses of HBIG vs. 73.2% for placebo groups). Anti-HBs developed in all infants of the treatment groups, indicating that HBIG did not interfere with active immunization.

This and other studies[669] indicate that HBIG given at the same time as hepatitis B vaccine provides optimal passive–active immunity for long-lasting prevention of the carrier state, and this dose is the current recommendation. Studies in adults also confirm that HBIG given before or simultaneously with the first dose of hepatitis B vaccine does not interfere with the antibody response to hepatitis B vaccine.[758] This approach will protect 85 to 95 percent of infants from perinatally acquired HBV infection.[150]

HBIG is not of value in the treatment of either acute[7] or chronic[558] hepatitis B infection.

Hepatitis B Immunoglobulin in Liver Transplantation

Liver transplantation in a patient infected with hepatitis B is associated with a high rate of its recurrence in the new liver and subsequent mortality (50% in 2 years). Intravenous HBIG has proved efficacy and dose-dependent response in the prevention of HBV recurrence after liver transplantation[164] and has been the mainstay of posttransplant prophylaxis of recurrent HBV since the early 1990s.[118] The HBIG doses needed to prevent reinfection are very high, and thus HBIG primarily is given intravenously.[680]

HBIG given intravenously or by the usual intramuscular route will reduce the rate of recurrence of hepatitis B.[582] In a retrospective analysis of 359 such transplants, hepatitis B recurrence was 74 ± 6 percent in 67 patients given no HBIG, 74 ± 5 percent in 83 patients given HBIG for 2 months, and 36 ± 4 percent in the 209 patients given HBIG for 6 months or longer.

Grazi and coworkers[264] reduced significantly the recurrence rate in HBsAg-positive, hepatitis B virus DNA–negative cirrhotic individuals undergoing liver transplantation with the use of HBIG for 1 year after transplantation; recurrence was noted in 8/10 controls (80%) and 4/25 HBIG-treated patients (16%). Several other reports are available.[677,679]

In addition to HBIG therapy, pretransplantation and posttransplantation antiviral drugs such as lamivudine are used. When administered in the immediate pretransplantation period to patients with a high viral burden, these drugs enhance the effectiveness of HBIG because less virus must be neutralized.[352,677] Long-term maintenance of antivirals with discontinuation of HBIG after several months may be feasible.[158,692,747]

Preliminary studies of monoclonal antibodies to hepatitis B antigens are under way.[763]

Recommendations

Prophylaxis. HBIG is recommended after a person's parenteral or mucous membrane (oral, sexual, ophthalmic) has contact with blood or body fluids from individuals with hepatitis B or with HBsAg-positive materials (e.g., blood, plasma) and for neonates born to HBsAg-positive mothers (see Table 245-5).[25]

Exposure to Blood That Contains (or May Contain) Hepatitis B Surface Antigen. No prospective studies have tested the efficacy of a combination of HBIG and hepatitis B vaccine in preventing hepatitis B after accidental exposure, including exposure by the percutaneous, ocular, and mucous membrane routes, or by human bites that penetrate the skin. Health care workers at risk for incurring such accidents should receive hepatitis B vaccine as preexposure immunization as the most effective means to prevent HBV transmission.[25] For unimmunized people the combination of HBIG and hepatitis B vaccine is recommended after significant accidental exposure (Table 245-6).

If the exposed patient is unimmunized and the blood or secretions come from an individual known to be HBsAg positive or if the infection status of the source is unknown but the source is at high risk, immediate prophylaxis is indicated. A single dose of HBIG 0.06 mL/kg, or 5 mL for adults, should be given intramuscularly as soon as possible, preferably within 24 hours of exposure.[25] Hepatitis B vaccine should be given simultaneously at a different site and repeated after 1 and 6 months (see Table 245-6). After massive exposure (i.e., by blood transfusion), much larger doses of HBIG may be indicated.

If the exposed patient has been immunized but the serologic response is not known, anti-HBs titers should be determined and the individual managed according to the results; if nonresponsive (anti-HBs <10 mIU/mL by radioimmunoassay), HBIG and a full series of vaccine should be given. In patients with a contraindication to vaccine, two doses of HBIG 0.06 mL/kg should be used, the second administered 1 month after the first. Two doses of HBIG also should be given to an exposed health care worker who is known to have no response to two series of hepatitis B vaccine.[25] Current recommendations from the CDC[146] for nonoccupational exposures are to administer vaccine alone to previously immunized individuals as a booster dose without the need to document serologic response if the exposed person has written documentation of a completed hepatitis B vaccine series. The *Red Book*[25] also agrees with this booster vaccine approach. We recommend a more individualized approach for assessing risks of the addition of HBIG.

Perinatal Exposure. Among mothers who are HBsAg positive and HBeAg positive, 85 percent of their untreated infants will become infected and be chronic carriers, and chronic hepatitis, cirrhosis, or hepatic cancer will develop in some of them. If the mother is HBsAg positive only, the risk for her offspring becoming a carrier is less but still significant. More than 90 percent of infants infected perinatally will develop chronic HBV infection.[25] Accordingly, these infants should receive HBIG prophylaxis and hepatitis B vaccine.

Infants Born to Mothers Who Are HbsAg Positive. For optimal passive–active immunity, HBIG 0.5 mL is given to the newborn at birth (preferably in the delivery room but within 12 hours at the latest). Hepatitis B vaccine (at

TABLE 245-6 **Hepatitis B Postexposure Recommendations for Hepatitis B Immunoglobulin and Hepatitis B Vaccine**

	HBIG		*Hepatitis B Vaccine*	
Type of Exposure	**Dose**	**Recommended Timing**	**Dose**	**Recommended Timing**
Perinatal				
Infant of HBsAg-positive mother	0.5 mL IM	Within 12 hr of birth	0.5 mL	First dose within 12 hr, repeat 2 times
Infant of mother whose HBsAg status is unknown	0.5 mL IM	Within 7 days of birth if mother is found to be HBsAg positive	0.5 mL	First dose within 12 hr, repeat 2 times
Premature infant (<2000 g) whose mother's HBsAg status is unknown	0.5 mL IM	Within 12 hr of birth (unless maternal HBsAg test result is negative by this time)	0.5 mL	First dose within 12 hr, repeat 3 times
Mucous Membrane or Percutaneous with Known Nonoccupational Exposure				
Nonvaccinated	0.06 mL/kg IM	Immediately	0.5 mL*	First dose immediately, repeat 2 times
Previously vaccinated, known responder	None	None	None	
Previously vaccinated, unknown response	0.06 mL/kg IM if HBs	Test patient for antiHBs; omit HBIG† if >10 mIU/mL	0.5	Give booster†
Previously vaccinated, known nonresponder	0.06 mL/kg IM	Immediately, may repeat in 1 month if <10 mIU/mL‡	0.5 mL*	Give booster immediately, repeat 2 times if necessary
Sexual: Known Exposure				
Nonvaccinated	0.06 mL/kg IM	Immediately, but no later than 14 days	0.5 mL*	First dose immediately, repeat 2 times
Vaccinated†	None	None	0.5 mL	Give booster if unknown response

*Dose for individuals younger than 20 years. The adult vaccine dose is 1 mL. The dose for immunosuppressed patients and patients undergoing dialysis varies with the vaccine used. Vaccine doses given are for Recombivax HB or Engerix-B.
†Recent CDC recommendations for exposure (sexual, sexual assault, percutaneous, or mucosal) from a source with unknown hepatitis B status are to forgo vaccine and HBIG if the exposed patient is already immunized and has written documentation of complete vaccine series and did not receive serologic testing for response. Individual assessments of potential risk must be made. See text.
‡See text for discussion of persons who have not responded to two vaccine series.
HBsAg, hepatitis B surface antigen; *HBIG,* hepatitis B immunoglobulin.

a dose of half the adult dose) is begun simultaneously and repeated at 1 and 6 months (see Table 245-5). This combination is only approximately 90 percent effective in preventing the carrier state because intrauterine infection will not be prevented.

Term Infants Born to Mothers Not Tested for HBsAG. If the HBsAg status of the mother is unknown, hepatitis B vaccine should be given to the term infant within 12 hours, and HBIG should be administered as soon as the mother is shown to be a carrier. Its effectiveness is diminished markedly if administration is delayed beyond 48 hours after birth but is recommended to be given up to 7 days after birth.[25]

The mother should be tested immediately. If she is HBsAg negative, the vaccine series is continued as recommended for other infants. If the mother is found to be HBsAg positive, HBIG and hepatitis B vaccine should be given to her infant, even if a significant delay has occurred. After the final dose of the vaccine series, the infant can be tested for HBsAg and anti-HBs at 9 to 18 months to determine the success of the HBIG and vaccine regimen. Testing should not be performed before 9 months of age to avoid detection of anti-HBs from HBIG administered during infancy and to maximize the likelihood of detecting late HBV infections.[25] If HBsAg is present, the infant is a carrier. If anti-HBs is present, the child was successfully immunized. Administration of HBIG at birth should not interfere with polio or DTaP vaccines starting at 2 months of age.

Premature Infants. Premature infants with birth weights less than 2000 g who are born to women not tested for HBsAg should be given HBIG 0.5 mL within 12 hours of birth unless the mother's HBsAg test result can be available within 12 hours and is negative. Immunization should be started immediately and repeated for a total of four doses (rather than the usual three doses) because of the poorer response of preterm infants to the vaccine.[25]

Sexual Exposure to Hepatitis B or a Carrier of Hepatitis B. Sexual exposure (including rape) to an individual who has hepatitis B or is a carrier is an indication for administration of HBIG 0.06 mL/kg intramuscularly (maximum, 5 mL) and initiation of hepatitis B vaccination. HBIG should be given as soon as possible but not after 14 days after exposure. If only HBIG is given, a second dose of HBIG is recommended after 30 days. The

CDC[146] also recommends booster vaccine alone in this situation if written documentation is available for a completed hepatitis B vaccine series.

Possible Exposure. After possible exposure (percutaneous, ingestion, sexual) to an unidentified person or body fluid in which the HBsAg status is unknown, the decision to treat with HBIG must be made individually on the basis of the likelihood that the source is HBsAg positive and the seriousness of the exposure. Hepatitis B vaccine should be initiated immediately if the exposed person is not immunized. Current *Red Book* recommendations and CDC recommendations[25] suggest that with an unknown source, vaccine alone is acceptable for an unvaccinated exposed patient and no treatment is required if the exposed person has written documentation of having previous immunization. We recommend a more individual approach to assess risks.

Ideally, the source subject should be tested for HBsAg positivity; if the results are available within 7 days for a percutaneous exposure and 14 days for a sexual exposure,[25] HBIG 0.06 mL/kg (maximum, 5 mL) can be given immediately and again at 1 month if the source is HBsAg positive and the patient did not or could not receive vaccine. When the source subject cannot be tested or when the source is likely to be HBsAg positive, HBIG is administered immediately.

If the exposed individual is a high-risk patient (e.g., immunodeficient, immunosuppressed, institutionalized, or undergoing hemodialysis) or is in an environment or health care unit for which past environmental control measures have been ineffective, HBIG should be given in addition to hepatitis B vaccine.

HBIG is not indicated on a routine basis after administration of blood transfusions. School or hospital exposure or usual household exposure is not an indication for HBIG, but household exposure is an indication for vaccine for unimmunized exposed persons.[25]

LIVER TRANSPLANTATION

For patients who are HBsAg positive at the time they undergo liver transplantation or in the rare situation in which the donor of the liver is HBsAg positive, administration of HBIG is recommended in the preoperative period and after transplantation to prevent recurrence in the transplanted liver.*

The exact dose, frequency, route, and duration of HBIG in this situation have not been established, but the dose is large and adds significantly to the cost of the transplant procedure.

The typical regimen is to use very high HBIG doses (i.e., 2000 IU [10 mL]/week) before transplantation and immediately after transplantation, along with antiviral medications.[677] The HBIG is continued for several months to years, and the dose is determined by monitoring of the hepatitis B viral burden by PCR. After several months, the HBIG may be reduced or discontinued, but the antivirals are continued.[747] (See earlier discussion.)

HEPATITIS C

Early studies suggested that lots of polyvalent IGIM or HBIG not screened for hepatitis C antibodies provided some protection against the acquisition of non-A, non-B hepatitis (presumably hepatitis C) after heart surgery or hemodialysis.[373,586,626]

Two studies provide some evidence for a prophylactic effect of IGIM. Piazza and colleagues[538] gave polyvalent IGIM (from pools containing antibodies to hepatitis C virus [HCV]) or placebo monthly for 4 to 20 months to the seronegative sexual partners of 884 patients who were seropositive for HCV. One of the 450 (representing 560 subject-years) in the IGIM group became infected versus 6/449 (500 subject-years) in the placebo group ($p = .03$; relative risk, 10.7). The authors concluded that sexual transmission of hepatitis C occurs and that IG has a protective effect.

Féray and associates[217] reviewed the records of 218 patients with hepatitis C coinfection undergoing liver transplantation who received an HBIG product that contained antibody to HCV. The incidence of HCV viremia 1 year after transplantation was significantly lower (25/46 [54%]) in patients receiving HBIG than in those not receiving it (162/172 [94%]; $p < .001$). They also reviewed 210 transplanted HCV-seronegative patients and found that hepatitis C developed within 1 year in 18/68 patients (26%) who received the HBIG product containing anti-HCV antibody in contrast to 40/86 patients (47%) who did not receive HBIG, a significant difference ($p < .001$) suggesting a preventive effect of hepatitis C antibodies.

Also supporting this concept was the observation that HCV was transmitted by pooled human IG in the early 1990s, shortly after HCV antibody–positive donors were excluded from the donor pool.[144,593] These antibodies presumably neutralized the small amounts of HCV present in the unscreened lots. Indeed, Yu and colleagues[757] demonstrated that HCV antibodies in unscreened IG lots containing HCV antibodies prevented low-dose infection in chimpanzees. Screened IGIM lots after 1991 lacking HCV antibodies did not prevent infection.

Because HBIG can prevent recurrence of hepatitis B among patients with hepatitis B undergoing liver transplantation,[264,583] researchers have postulated that hepatitis C antibodies might prevent recurrence in hepatitis C–positive liver transplant recipients. Current studies are ongoing to develop monoclonal antibodies, immunomodulators, and vaccines to effectively neutralize HCV.* Bavituximab is a monoclonal antibody that targets phosphatidylserine, a specific phospholipid component of cell membranes that become exposed on the outer membrane of cells infected with HCV. A phase I study demonstrated mild adverse events in six patients, and phase II trials are ongoing. It is also being studied for therapeutic use in patients with advanced solid tumors.[12]

Experimental Hepatitis C Immunoglobulin

Experimental HCV-IGIV is derived from human plasma units rejected for HBIG or IGIV manufacture because of the presence of hepatitis C antibodies: it does not contain hepatitis C, as tested by PCR.

Krawczynski and colleagues[382] showed that HCV-IGIV delayed but did not prevent experimental hepatitis C infection in chimpanzees in contrast to regular IGIV without hepatitis C antibodies.

Willems and colleagues[737] gave HCV-IGIV to 26 hepatitis C–positive liver-transplant recipients during the ahepatic and postoperative periods, without decreasing the rate of recurrence of hepatitis C. Davis and colleagues[179] reported a multicenter double-blind study of HCV-IGIV (Civacir, Nabi) in hepatitis C–positive liver-transplant recipients. No effect occurred on HCV RNA levels, but some decrease in liver enzyme activities in contrast to the control patients was noted. Thus, the use of antibody to prevent the development of hepatitis C after liver transplantation has not been successful and was attributed to limitations of dosing and the inability of HCV-IGIV to neutralize the HCV RNA in phase II trials.[179]

Recommendation

No passive immune product is available for hepatitis C prophylaxis.

HERPESVIRUSES

The common herpesviruses that cause human infection are CMV, Epstein-Barr virus (EBV), herpes simplex virus types 1 and 2, varicella-zoster virus, and human herpesviruses 6, 7, and 8. Although these DNA viruses produce latent infection that can reactivate, particularly in immunodeficient patients, the major uses of IGs have been in the prevention of primary varicella-zoster virus infection and prevention and treatment of CMV infection in transplant recipients and more recently in pregnant women and their fetuses with primary infection.

Cytomegalovirus

Use of Cytomegalovirus Intravenous Immunoglobulin or Intravenous Immunoglobulin in Transplantation

CMV infection remains a major complication after hematopoietic cell transplantation and solid organ transplantation. Seronegative individuals who receive an allograft from a seropositive donor are at the highest risk for acquiring CMV infection. Both polyvalent (IGIV) and hyperimmune CMV intravenous immunoglobulin (CMV-IGIV [CMVIG]) have been used since the 1980s to prevent development of CMV infection in bone marrow and solid organ transplant recipients.[744] Clinical trials in the 1990s demonstrated the efficacy of prophylaxis with IGIV in preventing CMV infection and pneumonia. CMVIG is prepared from the plasma of donors with high anti-CMV titers, but polyvalent IGIV also contains anti-CMV antibodies at lower titer. Early studies used CMVIG or IGIV alone, but later studies have combined IG with antiviral agents.

Early studies in renal and liver transplant recipients showed the efficacy of CMVIG or IGIV.[632] Two meta-analyses demonstrated decreased CMV mortality rates with the use of CMVIG or IGIV in bone marrow and solid organ transplant recipients.[746] Others have shown a similar prophylactic benefit of IGIV or CMVIG.[460,617] Ruutu and coworkers[578] showed no prophylactic benefit of CMVIG in CMV-seronegative bone marrow transplant recipients. A multicenter retrospective review[553] of CMVIG prophylaxis in addition to intravenous gancyclovir in pediatric lung transplant recipients did not demonstrate a decrease in either posttransplant CMV infection or morbidities.

Several factors that have reduced the need for CMVIG or IGIV in transplant recipients include the realization of a markedly reduced risk for development of CMV if both the donor and recipient are CMV antibody negative (D–/R–), the use of CMV-seronegative or filtered blood products, the early detection of CMV by PCR, and the use of ganciclovir-valganciclovir prophylaxis or early treatment.[285]

Snydman and colleagues,[631] in an open-label, multicenter study in liver transplantation, found that the combination of CMVIG and ganciclovir was superior to different immunosuppressive regimens in historical controls. Campbell and colleagues[127] recommended universal prophylaxis for the patients at highest risk, children receiving liver transplants (D+/R–), but the role of immunoglobulin was uncertain.

In heart and lung transplants, the use of CMVIG for CMV infection prophylaxis has been recommended by some groups if either the donor or the recipient is CMV seropositive. Weill and associates[725] showed that combined ganciclovir and CMVIG reduced the incidence of CMV infection in high-risk lung transplant recipients in contrast to historical controls. Ruttmann and colleagues[577] showed, in a retrospective study, decreased morbidity resulting from CMV infection in lung transplant recipients given both CMVIG and ganciclovir in contrast to the use of ganciclovir alone. A meta-analysis examining the use of CMV hyperimmunglobulin (CMVIG) for the prevention of CMV infection and disease in solid organ transplant recipients demonstrated that prophylactic administration of CMVIG was associated with improved total survival and a reduced frequency of CMV-related disease and deaths.[96]

Zamora and associates[761] recommended intravenous ganciclovir and CMVIG for all lung transplant recipients if either the donor or recipient is CMV seropositive; and in the situation of D+/R–, they gave seven infusions of CMVIG in the first 90 days after transplantation. Other investigators[96,176,698] and consensus statements[43,543] permit the use of combined therapy with CMVIG in high-risk heart and lung transplant recipients and other solid organ recipients, despite the absence of definitive controlled studies.

The use of IGIV for the treatment of hemophagocytic lymphohistiocytosis associated with CMV infection also has been reported.[308]

Use of Cytomegalovirus Intravenous Immunoglobulin in Perinatal Cytomegalovirus Infection

Another use of CMVIG may be the treatment of in utero CMV infection.[487] Two infusions of CMVIG were given intraperitoneally at 28 and 29 weeks' gestation to a CMV-infected fetus. The therapeutic benefit was unclear because the infant had intracranial calcifications at 2 weeks of age but was free of neurologic symptoms at 1 year of age. Matusuda and colleagues[442] and Sato and associates[589] used serial anti-CMV immunoglobulin injections into the fetal abdominal cavity to treat acute CMV infection in a fetus with a good fetal outcome.

Nigro and associates[491] treated a pregnant woman with primary CMV infection and in utero infection of one twin fetus with intravenous CMVIG at 30 weeks' gestation. CMVIG also was injected into the amniotic sac. The affected twin had better growth, decreased placental thickening, and lessened cord edema. Although born with CMV infection and hepatosplenomegaly, the child was normal at the age of 2 years.

Subsequently, Nigro and colleagues[489] gave 31 pregnant women with primary CMV infection at least one dose of CMVIG 200 U/kg during pregnancy. Ultrasonic evidence of CMV infection was seen in 15 fetuses. Nine women received additional CMVIG into their amniotic sac or umbilical cord. Only one woman gave birth to an infant with CMV infection in contrast to 7/14 women who did not receive CMVIG during pregnancy. All of these women had in utero infection confirmed by CMV-positive (culture or PCR) amniotic fluid. The infants of mothers who received CMVIG during the first half of the pregnancy were followed in a case-control study evaluating their outcome in contrast to that of 32 congenitally infected infants whose mothers did not receive CMVIG during pregnancy.[490] The risk for having a CMV-affected child with psychomotor retardation and hearing deficit was significantly higher in the untreated group, leading the authors to conclude that IG administered during the first half of pregnancy to women with primary CMV infection decreases neurologic sequelae associated with in utero CMV infection. Another group[710] compared infected infants born to women with primary CMV infection before 17 weeks' gestation who were treated with 200 U/kg of Cytotect (CMVIG product available in Europe) to those who were untreated and participants in a natural history study. At 1 year of age, 4/31 infants of Cytotect-treated mothers had poor outcome in contrast to that of 16 infants from 37 untreated mothers. Result from a double-blinded, randomized, placebo-controlled trial of Cytotect prophylaxis was recently presented; and review of the 122 subjects enrolled suggested protection against in utero fetal infection (44% in the placebo group vs. 30% in the treated group). Data also suggest that administration of IG may have an immunomodulatory effect on the placenta in addition to the neutralization of virus.[430]

Recommendations

Patients undergoing allogeneic human stem cell transplantation who are at risk for acquiring CMV disease (e.g., a CMV-seropositive recipient or a CMV-seronegative recipient and a CMV-seropositive donor) should receive either prophylactic antiviral therapy or preemptive antiviral therapy after early detection of infection by CMV PCR. Routine use of CMVIG no longer is recommended for prevention of CMV disease.[93]

Similarly, for solid organ recipients, the highest risk is a CMV-seropositive donor and a CMV-seronegative recipient, in which case antiviral prophylaxis is used. Antiviral prophylaxis rather than CMVIG or IGIV is used currently in kidney and liver transplantation.[328,602] In high-risk situations such as heart and lung transplants with either the donor or the recipient CMV seropositive, some centers use CMVIG in addition to antiviral therapy, despite lack of proof by multicenter, randomized studies.[96,543,698]

CMVIG or IGIV in combination with antiviral agents is used to treat severe CMV disease, such as pneumonia, in transplant recipients.[232,516,532,557,759] For CMVIG, 400 mg/kg on days 1, 2, and 7 and 200 mg/kg on days 14 and 21 have been used in addition to antiviral therapy,[557] although others have used a lower dose (100 mg/kg every other day for 2 weeks).[240] IGIV 500 mg/kg every other day for 10 to 59 days, followed by 500 mg/kg once or twice weekly for an extended period, also has been reported.[514] Garcia-Gallo and colleagues[234] reported the use of CMVIG as an adjunct to antiviral therapy to prevent development of pneumonitis in lung transplant recipients with invasive CMV disease and as preemptive therapy (with ganciclovir) in posttransplant recipients with persistent CMV viral load.

CMVIG for in utero CMV infection is not recommended routinely but several studies have demonstrated its safety and efficacy, and its use may be of value in selected situations with confirmed primary maternal infection or fetal infection.

Epstein-Barr Virus

EBV, the etiologic agent of infectious mononucleosis, causes severe infection in immunocompromised patients and males with X-linked lymphoproliferative syndrome. IGIV has been given to EBV-seronegative males with X-linked lymphoproliferative syndrome in an attempt to prevent EBV infection, but EBV infection developed in some of them despite IGIV adminstration.[222]

Transplant recipients with EBV-induced posttransplantation lymphoproliferative syndrome or hepatitis have been treated successfully with a combination of IGIV or CMVIG, antiviral therapy, and IFN-α.[182,500,670]

A similar approach was not successful in X-linked lymphoproliferative syndrome.[508] CMVIG was used in one case because it contains higher titers of anti-EBV antibody than IGIV.[182] One case of fulminant EBV hepatitis was treated successfully with liver transplantation, antiviral therapy, and CMVIG.[216]

A recent multicenter trial indicated that CMVIG given to liver transplant recipients did not prevent posttransplantation lymphoproliferative disease or other EBV disease.[265] However, the EBV serology was unavailable in 50 of the 82 donors, hampering interpretation of the results.

Ohta and colleagues[507] reported marked improvement of a patient with chronic EBV hepatitis after kidney

transplantation by treatment with the anti-CD20 monoclonal antibody rituximab after failure of reduction of immunosuppression. Rituximab has been used successfully in the treatment of EBV-induced posttransplantation lymphoproliferative disease in stem cell[213,614] or solid organ transplants.[159,291,298,673,754]

Rituximab also has been used in preemptive therapy in stem cell transplantation based on EBV viral load.[161,701] Boesch and colleagues[94] reported the successful use of rituximab to treat an adolescent without immunodeficiency who developed EBV-associated lymphoproliferative disease that involved massive submucosal infiltration of B cells in the lingual tonsils, trachea, and bronchi and resultant near-complete airway obstruction unresponsive to steroids. A 28-year-old recipient of an orthotopic liver transplant was successfully treated for EBV-related posttransplantation lymphoproliferative disease refractory to rituximab with antiviral therapy and IGIV.[686] Some centers use IG (IGIV or CMVIG) in addition to antiviral therapy as prophylaxis in high-risk transplant recipients.[266]

Recommendations

Current approaches to EBV-induced posttransplantation lymphoproliferative disease include reduction of immunosuppression and consideration of preemptive therapy or treatment with rituximab,[634] although antiviral medication, anticytokine therapy, chemotherapy, and immunotherapy all have been used. In a recent literature review, Giulino and colleagues[248] found evidence of a better response to rituximab in children in contrast to adults and suggested that rituximab may be appropriate as first-line therapy for posttransplantation lymphoproliferative disease in children. The role of IGIV or CMVIG in addition to the use of anti-CD20 monoclonal antibodies has not been clearly defined.

Herpes Simplex Infections

Neutralizing antibody has a protective effect in herpes simplex virus (HSV) infection in the newborn period. Mothers with a reactivated herpes infection during delivery are 10-fold less likely to transmit HSV to their newborn infants during vaginal delivery than are mothers with primary HSV infection at delivery, presumably because of the transplacental transfer of antiherpes antibody.[27,546] IGIV-containing HSV antibodies has not been used in the prevention of neonatal herpes infection, although Whitley[732] has proposed that HSV monoclonal antibody or hyperimmune IGIV be evaluated for treatment of disseminated neonatal disease.

Masci and colleagues[440] compared monthly IGIV 400 mg/kg with intermittent acyclovir treatment (800 mg twice daily, 1 week each month) in patients with recurrent genital HSV infection for 6 months and noted fewer recurrences in the IGIV-treated group.

Recommendation

IGIV is not currently recommended for the prevention or treatment of HSV infections.

Varicella-Zoster Virus and Varicella-Zoster Immunoglobulin

Immunoglobulin in Varicella

After success was achieved with IGIM in the prevention of measles and hepatitis, IGIM was evaluated for the prevention of varicella. Although Funkhouser[230] in 1948 showed some beneficial effects of standard IGIM in the prevention of varicella in an uncontrolled study, Greenberg and colleagues[268] and Schaeffer and Toomey[591] were unable to prevent chickenpox in exposed children with IGIM doses of 2.5 to 20 mL.

Others have reported anecdotal evidence for the efficacy of IGIM in large doses during the early stages of chickenpox and herpes zoster. These claims included prompt relief of pain in zoster[727] and rapid resolution of skin lesions.[403,564] However, even high-titer IG (zoster IG) does not prevent dissemination of herpes zoster.[644]

Ross[570] in 1962 gave 242 children IGIM in doses of 0.1 to 0.6 mL/lb within 3 days of exposure to chickenpox; 209 similarly exposed, uninjected children were used as controls. The attack rate was the same (97%) in both groups, thus indicating that IGIM does not prevent varicella under these conditions. However, with doses of IGIM above 0.2 mL/lb, the severity of the disease was reduced, as indicated by a decreased number of pox and reduced temperature. Children receiving the largest dose of IGIM (0.6 mL/lb) had maximal temperatures of 38.9° C (102° F) versus 41.1° C (106° F) for controls and 40 pox versus 207 for controls. Other investigators also have reported similar but uncontrolled observations that IG modifies the severity of chickenpox.[319,687]

Varicella-Zoster Immunoglobulin in Varicella

The prophylactic value of large IG doses in decreasing the incidence and severity of varicella led to a trial of high-titer plasma or IG preparations to prevent varicella.[61] These preparations include zoster IG (ZIG) and plasma (ZIP) from convalescing zoster patients and varicella-zoster IG (VZIG) prepared from high-titer plasma from normal adults.

Brunell and associates[114] in 1969 selected convalescing patients with zoster whose complement-fixing antibody titers were 1:256 or greater and prepared ZIG from their plasma; this material had titers considerably higher than did standard IG. Exposed children from six families in which chickenpox was occurring were given ZIG or IG at doses of 2 mL. In none of 6 children receiving ZIG did chickenpox develop, whereas it developed in all 6 children given IG. No antibody developed in the ZIG-treated group, thus indicating that the disease was prevented.

Because this dose did not prevent varicella in leukemic children or other high-risk patients, a larger dose (5 mL) was used in a later study to successfully modify or to prevent varicella in 8/9 high-risk children.[112,113] Severe varicella developed in 1 child given a less potent preparation of ZIG. These observations were confirmed in two later studies. Judelsohn and associates[340] gave ZIG to 56 exposed high-risk children; mild varicella occurred in 7 patients and was prevented in the others, most of whom

were susceptible, as determined by absence of serum antibody. Gershon and colleagues[242] gave ZIG to 15 seronegative high-risk exposed children; varicella was severe in 1, mild in 9, and subclinical in 5. Subclinical infection was determined by the acquisition of membrane antibody, as detected by fluorescent microscopy.

Orenstein and associates[513] studied 553 exposed, high-risk patients who received ZIG of two different titers (≥1:1280 vs. 1:2560). They found that the clinical attack rate after receipt of ZIG correlated with the type of exposure (varicella developed in 36% with household exposure, 7.7% with hospital exposure, and 0% with school exposure), the rise in antibody titer (45% of patients without a fourfold titer increase became ill in contrast to 22% of patients with a fourfold or greater rise in titer), and the titer of the administered ZIG (significantly more complications and deaths occurred in recipients of the lower titer ZIG).

Because of the limited supply of ZIG and ZIP, VZIG from normal adults became the commercially available product in the United States. Zaia and associates[760] compared the efficacy of ZIG and VZIG in immunocompromised children exposed to varicella. Varicella attack rates and the clinical severity in recipients of VZIG and ZIG did not differ significantly. A higher incidence of subclinical infection was indicated by the rise in antibody titer in ZIG recipients (31.3%) versus that in VZIG recipients (16%). A larger dose of VZIG (2.5 mL/10 kg vs. 1.25 mL/10 kg) reduced the frequency of subclinical infection (from 20% to 4.3%). Varicella developed in several high-risk patients with demonstrable serum antibody at exposure, thus indicating that history-negative, seropositive patients are at risk for development of clinical varicella-zoster infection and should be given VZIG regardless of antibody titer.

In 2006, VZIG became unavailable and was replaced by VariZIG,* which is similar to VZIG and is an immunoglobulin product made from human plasma and contains high levels of anti-varicella immunoglobulin, is approved for administration to high risk individuals following exposure.[149] IGIV and acyclovir prophylaxis are reasonable alternatives for postexposure prophylaxis if VariZIG is not available.

Intravenous Immunoglobulin in Varicella Prophylaxis

Paryani and colleagues[525,526] in 1984 observed that IGIV at doses of 4 mL/kg to 6 mL/kg resulted in serum varicella-zoster virus antibody titers comparable to those in patients receiving VZIG at standard doses. Subsequently, Chen and Liang[153] demonstrated that varicella was prevented by a single dose of IGIV at 200 mg/kg in five children with leukemia.

Immunocompromised patients who are receiving IGIV at 400 mg/kg are thought to be protected for 3 weeks after infusion and do not require additional VZIG on exposure.[38] However, Ferdman and Church[218] reported that varicella occurred in two patients (one was a 21-year-old woman) receiving 500 mg/kg of IGIV after exposure to varicella 7 and 11 days after infusion. Another child receiving 400 mg/kg IGIV developed varicella 9 days after infusion. Both had mild disease and responded well to acyclovir. They suggest that for patients with profound immunodeficiency, VZIG can be given in addition to IGIV. Kavaliotis and associates[355] found that an IGIV dose of 1 g/kg given within 6 to 24 hours of exposure was 90 percent effective in preventing varicella in an oncology unit, with no additional advantage noted with administration of VZIG. All of the children who contacted VZV received prophylactic treatment consisting of a single infusion of either 1) varicella-zoster immunoglobulin (VZIG) at a dose of 1 ml/kg (group A) or 2) intravenous immunoglobulin (IVIG) at a dose of 1 g/kg (group B) or 3) both VZIG + IVIG at the above-mentioned doses (group C).

Tokat and colleagues[683] described a 32-year-old man with severe varicella pneumonia that progressed to acute respiratory distress syndrome. IGIV 400 mg/kg for 5 days was given with a successful outcome.

Recommendations

The decision to administer VariZIG or IGIV or acyclovir to prevent chickenpox is based on the patient's susceptibility, the type of exposure, and the patient's immune competence.

Determination of Susceptibility. With the exception of bone marrow transplant recipients, most immunocompromised individuals with previous varicella infection are considered immune; however, their immune status should be confirmed with varicella antibody titers. Healthy adults reared in the United States are considered immune if they have a history of varicella, zoster, or vaccination. Immunocompromised children and adults without a history of varicella are considered susceptible because of their higher risk for development of severe infection. Bone marrow transplant recipients are considered susceptible regardless of the varicella history of the donor or recipient. If varicella or herpes zoster[437] develop after transplantation, the patient then is considered to be immune.[142,143]

An immunocompromised, unimmunized child without a history of chickenpox is considered susceptible even if antibody titers are present because receipt of blood products containing IG may result in transient seropositivity. Alternatively, such patients who received VariZIG may have had asymptomatic varicella with the subsequent development of varicella antibodies, yet they may not be protected on reexposure.[39] The value of antibody titer to determine susceptibility in these patients is controversial. However, oncology patients who have been vaccinated for varicella before illness and have been seropositive for varicella antibodies before receipt of blood products are considered immune and do not routinely need VariZIG. The severity of immune compromise is also a factor, and bone marrow transplant recipients are considered susceptible despite prior history of immunization or disease.

VariZIG is not recommended for immunodeficient patients who have been vaccinated in the past, provided

*VariZIG is available through FFF Enterprises: 800-843-7477, http://www.fffenterprises.com.

they previously were shown to have varicella antibody, even if they are seronegative at the time of exposure. These individuals are expected to have mild disease.[142] Verifying varicella immunity with antibody before forgoing VariZIG administration in this situation is a reasonable approach because administration of VariZIG can be delayed up to 10 days and remain efficacious.

Type of Exposure. Individuals residing in the same household as a patient with varicella, persons who have had face-to-face contact with a patient considered infectious, and patients sharing the same hospital room are considered to have significant exposure. Because the duration of exposure that results in transmission is not known, each exposure must be evaluated individually. Contact with a varicella vaccine recipient with a varicella rash must be considered a significant exposure for an immunodeficient patient because the vaccinee may have wild-type virus infection; vaccine strain virus rarely has been transmitted.[143]

Candidates for Varicella-Zoster Immunoglobulin or Intravenous Immunoglobulin

Normal Adults, Children, and Adolescents. Normal children, adolescents, and adults exposed to chickenpox or zoster usually are not candidates for receiving VariZIG or IGIV (Table 245-7). Because of the prolonged incubation period for varicella the chickenpox vaccine may be given if the exposed individual is older than 12 months.

Immunocompromised Children and Adults. The principal use of VariZIG is to prevent chickenpox in susceptible immunocompromised children exposed to zoster or chickenpox (see Table 245-7). These children include those with primary immunodeficiency and those with secondary immunodeficiency, including HIV infection and neoplastic disease, and those receiving immunosuppressive therapy (e.g., systemic steroids and chemotherapy).[50,502,513]

Susceptible pregnant women are also candidates for VariZIG because of their increased risk for development of severe varicella pneumonia.[401,630]

TABLE 245-7 **Candidates for Varicella-Zoster Immune Globulin (VariZIG) After Significant Exposure**

Immunocompromised children without a history of varicella and without documented response to immunization*
Susceptible, pregnant women
Newborn infants whose mother had an onset of varicella within 5 days before delivery or within 48 hours after delivery
All hospitalized premature infants born at <28 weeks' gestation or <1000 g at birth, regardless of maternal history
Hospitalized premature infants of >28 weeks' gestation whose mother has no history of chickenpox or who is seronegative; may consider its use for other premature infants. See text.

*Severity of immune compromise is a factor in the decision to give VariZIG despite immunization and disease history. See text.

Term and Premature Newborns. Newborns who acquire varicella after birth are not at high risk for development of severe disease and are not candidates for receiving VZIG, with the possible exception of those whose mothers have severe skin disease.[401] Newborn infants born to mothers in whom varicella developed within 5 days before delivery or within 2 days after delivery are at high risk for having severe varicella because they have not received transplacental protective antibodies.[142] Others, questioning the validity of these limits, have treated a small number of infants born to mothers in a window ranging from 7 days before delivery to 5 days after delivery with IGIV 500 mg/kg and a prophylactic acyclovir regimen.[312]

Exposed hospitalized premature infants born at less than 28 weeks' gestation or less than 1000 g should receive VariZIG. These infants are susceptible, regardless of the maternal history of varicella, because of incomplete transplacental transfer of maternal antibody. Hospitalized premature infants with significant exposure who were born at more than 28 weeks' gestation and whose mothers do not have a history of varicella or are seronegative also are considered candidates for receiving VariZIG because transplacental antibody would not be present.[142,401,437]

Gold and colleagues[254] showed that gestational age of more than 28 weeks and birth weight above 1000 g do not always accurately predict the presence of maternal varicella antibody. Ogilvie[502] suggested that infants born before 30 weeks' gestation be given VariZIG and that some infants born after 28 weeks will lose their maternal antibody by 60 days of age; she recommends antibody testing on exposure if it can be performed quickly to assess the need for passive immune prophylaxis. Linder and colleagues[415] also noted that only 24 percent of premature neonates born at 29 to 35 weeks had positive fluorescent antibody to membrane antigen (FAMA) titers at 2 months of age.

Gold and associates[254] recommended the routine use of VariZIG in the neonatal ICU if the FAMA assay is not available to determine susceptibility. Previous administration of blood products in the neonatal ICU may render these results uninterpretable.

Dosage. The VariZIG brand of VZIG is supplied in lyophilized vials of 125 U (reconstituted to a 5% solution for intramuscular use). The dose of VariZIG is 125 U/10 kg intramuscularly. The minimal dose for infants is 125 U (one vial), and the maximal dose is 625 U for adults (five vials).[38,147]

Although VariZIG should be given to susceptible candidates as soon as possible after exposure for maximal protection, it can be given up to 10 days after exposure.[133,149] A second dose is not needed for subsequent exposure unless it occurs beyond 3 weeks after administration of the VariZIG dose.[39] IGIV 400 mg/kg is an acceptable alternative if the child has a bleeding diathesis and cannot receive intramuscular injections or if VariZIG is not available.[142]

VariZIG is not recommended for the treatment of chickenpox, zoster, disseminated varicella, or postherpetic

neuralgia; zoster IG did not prevent dissemination of zoster in immunocompromised patients.[644]

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The rationale for use of IGIV in patients with advanced HIV disease is their increased susceptibility to common bacterial and viral infections, poor primary antibody responses to vaccine antigens despite hypergammaglobulinemia, and, in young children, a limited antibody spectrum to common bacterial pathogens. Although the central immune defect in acquired immunodeficiency syndrome (AIDS) is a loss of helper T-cell ($CD4^+$) number and function, the polyclonal B-cell activation and defective helper T-cell function result in a significant B-cell deficiency.[81,496]

Thus, in children with AIDS, bacterial infections occur more commonly than opportunistic infections. Immune-mediated thrombocytopenic purpura and viral diseases (e.g., RSV and parvovirus and other disorders amenable to IGIV prophylaxis or therapy) also may develop in patients with AIDS.

After preliminary uncontrolled studies suggested a benefit of IGIV in children with advanced HIV infection,[126,619] two large multicenter controlled studies undertaken by the National Institutes of Health–supported Pediatric AIDS Clinical Trial Group determined the efficacy of IGIV in decreasing infections and improving survival in AIDS patients.[484,638]

In the first study, 372 children received 400 mg/kg of IGIV every 4 weeks or an albumin control for 2 years.[484] Thirty percent of all children in the IGIV-treated group had serious infections in contrast to 42 percent in the placebo group. Children who were less ill (those with $CD4^+$ lymphocyte counts >200/mL) benefited in particular from IGIV. Children in this category had fewer serious infections and were hospitalized less frequently than those in the placebo group, and their $CD4^+$ counts dropped less rapidly than those of the placebo group.[466] The mortality in both groups, however, was identical. Children with $CD4^+$ counts less than 200 cells/mL (i.e., those with severely impaired immunity) who were given IGIV had no significant decrease in infections, days of hospitalization, or mortality in contrast to their counterparts in the placebo group.

The authors concluded that IGIV significantly reduced the risk for development of serious infection in some children with symptomatic HIV infection, primarily those with $CD4^+$ counts between 200 and 500 cells/mL. In a follow-up study, the placebo group was allowed to cross over to receive IGIV, with a drop in the rate of serious infections and hospitalizations.[469]

In a second trial of IGIV in which all the children received zidovudine, a significant decrease in serious bacterial infections was found again, but this benefit was limited to children who did not receive trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis jiroveci* pneumonia.[638] A consensus of an HIV Working Group[750] was that HIV-infected children with significant hypogammaglobulinemia or documented poor antibody formation may be candidates for receiving IGIV therapy. IGIV also may be of benefit to HIV-infected children who have recurrent infections not controlled by antibiotics or chronic nonspecific diarrhea with failure to thrive.

IGIV also was shown to prevent serious infections in adults with advanced HIV infection.[369]

In addition to preventing serious bacterial infections, IGIV given to children with HIV infection reduced the number of nonserious bacterial infections (by 60% for ear infections, 13% for skin infections, and 10% for other upper respiratory tract infections) and viral infections by approximately a third in both trials.[463,465,467,638] In an additional study, 135 children with symptomatic and asymptomatic perinatally acquired HIV infection in addition to uninfected infants were given monthly IVIG infusions over 12 months. The authors found significant reductions in the frequency of common bacterial infections in the HIV-symptomatic group in contrast to both the asymptomatic and the control groups.[509]

A recent study showed that monthly IGIV could be safely discontinued in children who are clinically stable and receiving highly active antiretroviral therapy (HAART).[270]

Regular IGIV infusion also improved left ventricular function in HIV-infected children with dilated cardiomyopathy.[416] It is also effective in treating certain other complications of HIV infection, including thrombocytopenia,[123,395] red cell aplasia after associated with parvovirus B19 infection,[377] Guillain-Barré syndrome,[247] and certain drug reactions.[221] IGIV, even in high doses, provides no antiviral activity to HIV.[511]

Attempts to use HIV-specific antibody to prevent HIV infection or to provide an antiviral effect have met with very limited success.

These studies have used human immune plasma or hyperimmune HIV IG (HIVIG) from asymptomatic HIV-seropositive patients, porcine antisera, or monoclonal antibodies.[651] In two of three controlled clinical trials of immune plasma in adult patients with AIDS, a modest clinical benefit was achieved, as judged by decreased opportunistic infections, a slight increase in $CD4^+$ cell counts, and improved survival; however, no striking decreases in viral burden were noted.[323,409,713]

In a double-blind, placebo-controlled multicenter study, HIV-seropositive pregnant women receiving zidovudine were given HIVIG monthly during the last trimester of pregnancy, and their newborns were given one HIVIG dose at birth; no effect on the rate of maternal-fetal HIV transmission versus that in a similar group given regular IGIV was found.[650] The rate of transmission in both groups was unexpectedly low (<5%), so the study was discontinued after 800 patients had been enrolled because the study was not statistically powered to detect a slight reduction in transmission rates.

Another study examined the antiviral effect of large doses of HIVIG in 30 children with moderately advanced HIV infection who were receiving stable antiviral treatment and showed a measurable viral burden.[649] No striking beneficial effect was observed as indicated by plasma HIV RNA levels, cellular viral culture titers, or immunologic assays.

Despite these failures, efforts to develop antibody preparations that will neutralize the virus continue; such preparations would be particularly valuable after needlestick, perinatal, or sexual exposure.[649] Under study are monoclonal antibodies to neutralizing regions of the virus, antibodies to coreceptors that may interfere with HIV attachment, and combinations of antibodies with different specificities, including combinations of HIVIG with monoclonal antibodies.[46,121,394,412-413,521] An effective neutralizing antibody also would provide valuable information toward an effective vaccine.

Recommendations

IGIV may be beneficial in symptomatic children with HIV infection to prevent bacterial and viral infections and treat certain complications (e.g., thrombocytopenia, anemia of parvovirus infection, and autoimmune hemolytic anemia [Duncan syndrome]) but has no direct antiviral activity. Because the administration of HAART plays a critical role in the reconstitution of the immune system, specifically the cellular immune system and resultant increase in humoral immunity, additional passive immunity administered with IGIV has not been shown to be of substantial benefit in children with well-controlled HIV infection. HIVIG or plasma derived from infected patients has little or no antiviral activity or clinical benefit for HIV-infected adults or children, and the administration of HIVIG during pregnancy was not shown to provide added reduction in maternal-fetal transmission of HIV.

Monoclonal antibodies directed against the virus or its cellular receptors show considerable promise but are not yet available.

MEASLES

The first successful prophylaxis of measles with convalescent serum was reported by Cenci in 1907.[113] Convalescent serum was used in the United States first in 1916 by Park and Freeman[522] and Zingher,[767] who gave either 4 or 8 mL of serum to 41 recently exposed children at New York Metropolitan Hospital. Measles did not develop in any of the 20 children who received the 8-mL dose and developed in only 3 of the 20 children who received the 4-mL dose. In 1926, Park and Freeman[522] found that 6 to 10 mL of convalescent serum was 92 percent efficacious in preventing measles in recently exposed individuals, a finding confirmed and extended by Stillerman and associates.[652] Placental extracts containing serum antibodies also were used in the prevention and modification of measles.[450]

Stokes and colleagues[654] and Ordman and associates[512] both confirmed in 1944 that IG given immediately after exposure could prevent or modify measles and given in the early stages of clinical illness could lessen its severity. In 1955, Greenberg and coworkers[269] noted a lower incidence of measles encephalitis in IGIM-modified measles.

A major use of IGIM in the 1960s was to diminish the side effects of the Edmonston strain of measles vaccine. In 1962, Krugman and associates[389] noted that the simultaneous administration of 0.02 mL/lb of IG at the time of Edmonston measles vaccination reduced the incidence of high fever from 40 to 14 percent and the incidence of rash from 10 to 2 percent. The mean titer of measles antibody achieved was somewhat reduced by the IGIM, and a slight decrease in the rate of seroconversion was noted; nonetheless, the vaccine–IGIM combination was 95 percent effective.[657] The current measles vaccine is less reactogenic and does not require concomitant IGIM injections.

Audet and colleagues[54] report that the measles neutralizing antibody titer in recent IGIV lots is decreasing because of the lower titer of vaccine-induced antibodies in contrast to natural infection among donors. Although not tested, IGIM probably has lower titers of measles antibodies, so that the recommended prophylactic doses may be inadequate.

Recommendations

IGIM or IGIV can be given to susceptible contacts within 6 days of exposure to prevent or to modify measles.[28] Infants younger than 1 year, immunocompromised patients, and pregnant women are at risk for development of severe disease and should receive immunoprophylaxis. Because HIV-infected patients with significant immunodeficiency may contract measles after exposure despite receiving immunization, they should also receive passive immunoprophylaxis.[241] IGIM is not recommended for healthy household or other close contacts if they have received at least one measles-containing vaccine unless they are immunocompromised. Measles vaccine has some efficacy if it is given within 72 hours of exposure and is preferred for the management of outbreaks in healthy individuals older than 1 year of age.[28]

The standard dose of IGIM is 0.25 mL/kg for healthy patients and 0.5 mL/kg for immunocompromised patients. The maximal dose is 15 mL. IGIV at comparable doses also can be used, but titers may be diminished in recent years.[54]

Immunodeficient children receiving regular IGIV treatments at doses of at least 400 mg/kg should be protected for up to 3 weeks after administration.[28]

Administration of IGIM to a healthy infant precludes the use of measles vaccine for 5 months if the dose was 0.25 mL/kg and 6 months if the dose was 0.5 mL/kg. For larger doses, longer intervals are needed (e.g., 8 to 11 months).[28]

IGIV in addition to other immunomodulators also has been used for treatment of acute measles infection[478] and in subacute sclerosing panencephalitis (SSPE), a delayed, rare degenerative neurologic disease complicating wild-type measles infection.[256]

MUMPS

Mumps IG was shown to have limited efficacy as postexposure prophylaxis, and this product no longer is manufactured in the United States.[29,168]

PARVOVIRUS

Human parvovirus B19, also termed *erythrovirus*, the cause of the benign childhood exanthem termed *fifth disease*, may also cause polyarthropathy, transient aplastic crises in patients with hemolytic anemia, chronic red cell aplasia in immunocompromised patients, and hemophagocytic syndrome.[109,317,755] Patients susceptible to chronic parvovirus infection include those with congenital[674] or acquired immunodeficiencies,[160,377] those receiving immunosuppressive therapy,[212,755] and organ transplant recipients.[349,435] In utero parvovirus infection can result in hydrops fetalis.[685] The use of parvovirus DNA PCR has facilitated establishment of the diagnosis in immunodeficient patients unable to make antibodies or in patients who have passively acquired parvovirus antibodies.

Parvovirus B19 has tropism for marrow erythroid progenitor cells because these cells express the blood group P antigen, the cellular receptor for the virus. Most adults have encountered and made antibodies to parvovirus, and thus IGIV is an excellent source of anti–parvovirus B19 antibodies.[598] IGIV has been used successfully to treat parvovirus-induced red cell aplasia.[396] Successfully treated patients have decreased viremia, reticulocytosis, and resolution of the anemia within 2 weeks. Sometimes relapse or persistent infection occurs, requiring maintenance IGIV therapy, particularly in patients with HIV infection and low $CD4^+$ cell counts.[376]

For treatment of chronic infection in immunodeficient patients, IGIV therapy often is effective and should be considered.[30,219] IGIV has been used successfully to treat parvovirus B19 anemia resulting from chemotherapy,[452] rituximab therapy,[609] or both.[322,635] However, IGIV was not of value in four children with persistent parvovirus infection undergoing chemotherapy for acute lymphocytic leukemia.[219] IGIV also has been used successfully for treatment of parvovirus B19 anemia in renal transplant recipients.[157,436,517,633]

Viguier and coauthors[709] administered 1 g/kg of IGIV for 2 days to treat successfully a 33-year-old woman with parvovirus B19–associated polyarteritis nodosa and fever, palpable purpura, intense myalgia, paresthesias, and polyarthritis of the hand joints. IGIV has been used with success in parvovirus B19–associated chronic fatigue syndrome in three adults[366] and one teenage boy.[449]

IGIV has been used as a supplement to transfusions in severe in utero parvovirus infection with hydrops fetalis. Selbing and coworkers[601] described a 24-week pregnant woman with severe preeclampsia whose fetus had ascites and pericardial effusion. She was given 25 g of IGIV, with resolution of the ascites, effusion, and anemia. Matsuda and colleagues[443] treated a parvovirus B19–infected hydropic fetus with two injections of IG into the fetal peritoneum, with resolution of the anemia and the hydrops.

Rugolotto and colleagues[574] treated an anemic newborn secondary to intrauterine parvovirus infection with IGIV 1 g/kg every 3 weeks for 8 months. Heegaard and coauthors[293] reported similar success of IGIV, in addition to in utero transfusions. Earlier attempts to treat older infants with persistent parvovirus-induced congenital anemia with IGIV were unsuccessful.[110]

Dennert and colleagues[183] performed a pilot study on the use of IGIV for 17 patients with chronic dilated cardiomyopathy and a significant parvovirus B19 viral load in endomyocardial biopsies demonstrating significant reduction in viral load and improvement in cardiac function. IGIV has also been used to successfully treat fulminant hepatitis resulting from parvovirus B19 in a 2-year-old Chinese boy.[129]

Human neutralizing monoclonal antibodies have been generated from infected individuals[245] for possible future therapeutic use.

Recommendations

Red cell aplasia caused by parvovirus infection in immunodeficient patients, including those with HIV infection, should be treated with IGIV 400 mg/kg/day for 5 days or 1 g/kg per day for 2 days.[109,377,472] If relapse is likely to occur because of the patient's severe immunocompromised status, IGIV 400 mg/kg can be given every 4 weeks.

Neonates with persistent congenital anemia caused by parvovirus B19 should receive IGIV 400 mg/kg for 5 days, with additional doses given if the anemia does not resolve.

Pregnant women carrying fetuses with in utero hydrops fetalis caused by parvovirus B19 infection also may be candidates for IGIV therapy.

RABIES AND RABIES IMMUNOGLOBULIN

Rabies is the ideal disease for passive immunization because the exact moment, the exact source, and the exact location of exposure usually are known. Furthermore, the long incubation period and the fact that the virus remains localized to the wound for several days enhance the effectiveness of passive immunization. Although a rabies serum was prepared initially in 1889 by Babes and Lepp,[55] experiments of Habel[282] in mice, guinea pigs, and monkeys involving the use of rabbit hyperimmune serum demonstrated that antibody worked by two mechanisms: (1) neutralizing the virus while it is still in tissues and (2) retarding the spread of virus within the nervous system, thereby prolonging the incubation period and permitting active immunity by vaccine to become established.

On the basis of these studies, a World Health Organization (WHO) Expert Committee in 1950 recommended that a field trial of the efficacy of hyperimmune rabies serum in conjunction with vaccine be conducted.[208] It was undertaken in Iran because multiple bites by a single rabid wolf coming into isolated villages were not uncommon occurrences, and this severe exposure had an associated 40 to 50 percent mortality. In 1954, a single rabid wolf bit 27 individuals, 17 of whom were bitten on the head. These 17 were divided into three groups: 5 received vaccine alone, 7 received vaccine and one dose

of antirabies serum, and 5 received vaccine and two doses of antirabies serum.[65] Of 5 persons treated with vaccine alone, 3 died of rabies; 1/7 in the one-dose antiserum group died, and 0/5 in the two-dose antiserum group died.

Antibody studies conducted on these patients indicated that a single or double dose of antiserum, followed by 14 to 21 daily doses of vaccine, results in significant levels of circulating antibody for as long as 50 days.[283] The antibody found early is supplied passively; after the 10th day, the antibody present is a result of the vaccine. Thus, optimal treatment requires both passive and active immunization.

Before 1971, the only available antiserum was of equine origin. It is still the only product available in some countries. Since 1971, human rabies IG (RIG) has been available in the United States and many other countries and is preferred because of the lessened risk for serum reactions.[620] In addition, human antibody has a half-life in the circulation twice that of equine antibody, with the result that higher levels of passive antibody are maintained. However, the antibody response to the vaccine given concomitantly is suppressed more effectively.[417]

A case of fatal rabies was reported in a 19-year-old man bitten on the finger by a rabid mongoose despite the recommended postexposure prophylaxis (RIG and five doses of human diploid cell rabies vaccine).[613] Possible reasons for failure included (1) inadequacy of the recommended dose of RIG; (2) vaccine injection into the gluteal region, where more fat is found than in the recommended deltoid region; and (3) decreased antibody response to the vaccine as a result of a possible immunodeficiency state.

Prevention of rabies consists of three essential components: thorough washing of the wound with a 20 percent soap solution followed by irrigation with povidone-iodine,[86,576] passive immunization with rabies antibody, and active immunization. Although most cases of failure are caused by lack of adherence to these three strategies,[539] isolated cases of rabies occurring despite appropriate management have been reported.

Wilde and associates[736] reported failure of prophylaxis in five Thai children who received multiple bites on the face and head; they suggested that failure to infiltrate all wounds with RIG and surgical closure before the wound was infiltrated might have been factors. Hemachudha and coauthors[295] reported failure of prophylaxis in a child with minor scratches on the nose and in a woman with a deep wound on the cheek; they suggested that direct inoculation of virus into nerve endings may have occurred.

Goudsmit and associates[257] found that a human monoclonal antibody combination was equivalent to RIG when it was used with vaccine in a hamster model of rabies. Bakker and colleagues[58,59] reported clinical data from two phase I studies evaluating monoclonal antibody cocktail CL184 against rabies for the use in resource limited areas where there is no access to human or equine rabies immunoglobulin.

Two phase 2 trials have been completed in the United States and the Philippines, and a third is currently being conducted in India.[99,252]

Recommendations

Human RIG is recommended in nonimmunized individuals for all bites by animals in which rabies cannot be ruled out and for nonbite exposure to animals proved to be or suspected of being rabid.[28,138] Such treatment should be given as early as possible after exposure and followed by vaccine administration. Decision to administer postexposure prophylaxis should be based on guidelines.[31] Two human RIG products are available in the United States—BayRab and Imogam Rabies-HT; both are prepared from the plasma of hyperimmunized donors. The recommended dose of 20 IU/kg of RIG must not be exceeded because higher doses can suppress immunologic response of the simultaneously administered vaccine.

The entire dose of RIG should be infiltrated around the wounds as soon as possible after the bite.[482]

If this is not anatomically feasible, any remaining RIG should be given intramuscularly.[31]

Wilde and colleagues,[736] recognizing the difficulty in infiltrating multiple wounds with a small volume of RIG, suggested dilution of the RIG. The WHO[751] recommends dilution of the RIG twofold to threefold in saline to ensure an adequate volume for infiltration. RIG should not be frozen, and if it is frozen, it should not be used. In addition to passive immunization with RIG on the first day of treatment, exposed patients should receive active immunization with rabies vaccine in four doses over 2 weeks.

Purified equine RIG–containing rabies antibodies may be available outside the United States and is associated by a low rate of serum sickness (<1%). Equine RIG is administered at a dose of 40 IU/kg, and desensitization before administration may be required.

Administration of one of the three vaccines licensed in the United States should be started at the same time as RIG; however, the vaccine and RIG should not be administered in the same syringe or with the same syringe or needle. Only two of the licensed vaccines are currently produced and available in the United States, human diploid cell rabies vaccine and purified chicken embryo cell vaccine. The vaccines are equally effective and administered in multiple separate doses. Vaccine should be given in the deltoid muscle or, for an infant, in the anterolateral aspect of the thigh and at an anatomic site removed from the injury or any injection sites of RIG. The vaccine should be administered on days 0, 3, 7, and 14 after exposure, with day 0 as the day of initial presentation. This new schedule replaces the previously recommended schedule that included a fifth dose administered on day 28.[28]

If RIG is not available immediately, immunization should be started and RIG given if it is available within 7 days.[31,138,482]

If vaccine is not available immediately, RIG should be administered and the vaccine given as soon as possible. If both RIG and vaccine are delayed, both should be given whenever available, regardless of the interval between exposure and treatment.[31,138,482]

The administration of passive antibody can inhibit the response to rabies vaccines; therefore, the recommended dose should not be exceeded. Vaccine never should be

administered in the same parts of the body or with the same syringe used to give RIG. Hypersensitivity reactions to RIG are rare.

RIG is not recommended for patients who previously received a full postexposure vaccine course of human diploid cell rabies vaccine, rabies virus adsorbed, or purified chicken embryo cell vaccine; who have received a three-dose preexposure intramuscular series of these vaccines; who have received a three-dose preexposure intradermal human diploid cell rabies vaccine used in the United States; or who have been immunized with any vaccine and have a documented rabies titer.[31,138,482]

Postexposure prophylaxis of immunodeficient patients is problematic. Jaijaroensup and coauthors[326] reported poor or nondetectable neutralizing antibody in five HIV-infected patients who received intradermal vaccine and proposed that higher doses of vaccine or additional boosters be considered. Serologic failure of both preexposure and postexposure rabies immunizations in children with HIV infection[519,681] has been reported. The number of doses of rabies vaccine recommended for people with altered immunocompetence has not changed; for such people, postexposure prophylaxis should be continued to comprise a five-dose vaccination regimen with one dose of RIG.

RIG is not indicated for the treatment of rabies. Hemachudha and colleagues[296] described a patient with rabies who developed total limb and facial paralysis after receiving RIG.

RESPIRATORY SYNCYTIAL VIRUS

Acute RSV infection of the respiratory tract is the most common cause of hospitalization of infants and young children and thus a significant public health expense. For high-risk patients such as premature infants and infants with chronic lung disease, RSV infection can be severe and life-threatening. The observation that passively transferred maternal antibody provided some protection from RSV infection[503] led to the development of passive immunity products to prevent and to modify the severity of infection. No effective vaccine exists.

Respiratory Syncytial Virus–Intravenous Immunoglobulin

The first immune modulator used for the prevention of RSV infection was RSV-IGIV (RespiGam), a 5 percent polyclonal human intravenous IG prepared from healthy donors with high RSV-neutralizing antibody titers. RSV-IGIV was licensed in 1996 after studies in high-risk infants demonstrated its efficacy. Groothuis and colleagues[271] conducted a prospective, blinded, randomized trial at five centers and showed that 58 premature infants who received RSV-IGIV at 750 mg/kg/month during the winter months had a significantly lower incidence of RSV lower respiratory tract disease than that observed in 58 premature control infants who did not receive RSV-IGIV (6.9% vs. 24.1%; $p = .01$). The RSV-IGIV–treated patients also had a lower incidence of moderate-to-severe RSV lower respiratory tract disease ($p = .006$), fewer days of hospitalization ($p = .020$), and fewer days in the ICU ($p = .05$).

Another large RSV-IGIV multicenter, double-blind, placebo-controlled study[545] of 510 infants with either prematurity or bronchopulmonary dysplasia also demonstrated a decreased number of hospitalizations (13.5% vs. 8.0%; $p = .047$), decreased total number of RSV hospital days ($p = .045$), and decreased days with oxygen use ($p = .007$). RSV-IGIV also decreased days of hospitalization for any respiratory illness by 38 percent and total respiratory illness hospital days by 46 percent, presumably because of antibodies to other respiratory pathogens.

An added benefit of RSV-IGIV prophylaxis was a decreased incidence of otitis media (number of episodes, 0.15 per patient vs. 0.78 per control; $p = .003$).[289,622]

In 1997, the American Academy of Pediatrics recommended RSV-IGIV for high-risk children with prematurity or bronchopulmonary dysplasia[40] but not for infants with cyanotic congenital heart disease[272,625] because of the risk for development of serious side effects. RSV-IGIV no longer is available.

Palivizumab

In 1996, palivizumab (Synagis), a humanized IgG1 monoclonal antibody against the fusion (F) glycoprotein of RSV,[250,659] entered clinical trials. Palivizumab neutralizes both type A and type B RSV and is 50 to 100 times more potent than RSV-IGIV.[585] A multicenter, randomized, double-blind, placebo-controlled study of 1502 high-risk infants (premature infants and infants younger than 2 years with bronchopulmonary dysplasia) demonstrated the efficacy of 15 mg/kg of palivizumab given intramuscularly every 30 days.[316] It resulted in significantly decreased number of RSV hospitalizations (55%; $p < .001$), RSV hospital days ($p < .001$), and days of oxygen therapy ($p < .001$).

Palivizumab was licensed in 1998, the first monoclonal antibody approved for the prevention of an infectious disease. Postlicensure studies also have supported its effectiveness.[533,568,627] Although debate continues about the cost-effectiveness of palivizumab in some countries,[358,510,664] palivizumab prophylaxis for high-risk infants is now the standard of practice in the United States.[20]

In 2003, Feltes and colleagues[215] reported the results of an international, randomized, double-blind, placebo-controlled trial of palivizumab prophylaxis in 1287 children with congenital heart disease. This study showed a 45 percent reduction in RSV hospitalizations, a 56 percent reduction in total number of hospital days, and a 73 percent reduction in total number of hospital days with oxygen with the use of palivizumab. European cardiologists and the American Academy of Pediatrics recommend use of palivizumab for infants with hemodynamically significant heart disease (uncorrected, partially corrected, or with residual disease), pulmonary hypertension or chronic lung disease, and hemodynamically significant dilated or hypertrophic cardiomyopathy causing cyanosis or requiring cardiac medication.[35,684]

The use of palivizumab for more than one season has been a concern because of the theoretical risk for side

effects resulting from the development of an antibody to the murine component.[399,494] Null and colleagues[494] found that only one child of 55 receiving palivizumab for a second season developed an antipalivizumab titer of greater than 1:40. This child had a titer of 1:160 on day 30 that fell to 1:10 on day 120 (30 days after the fourth injection), suggesting a nonspecific reactivity. No associated adverse events occurred, and the palivizumab trough concentrations were as expected.

Palivizumab or other RSV antibodies are not indicated for the treatment of RSV infection, although some have used palivizumab for treatment of adult and pediatric patients in high-risk settings.[152,368,603] Saez-Llorens and colleagues[580] found in a small pharmacokinetic study that although palivizumab was safe, it was of no clinical benefit for previously healthy children with acute RSV infection. Banna and colleagues[66] successfully used palivizumab and steroid therapy to treat an adult woman with RSV-related pneumonia after stem cell transplantation. An experimental RSV monoclonal antibody (Medi-493), given intravenously, was not of benefit for intubated patients with RSV infection and respiratory failure.[433] Studies of high-titer monoclonal antibodies may yield different results.[228,592,603]

Passive Immunity in Respiratory Syncytial Virus Treatment

Although a single dose of 1500 mg/kg of RSV-IGIV was of no benefit in normal and high-risk children with RSV infection,[568,566] DeVincenzo and associates[185] gave a single dose of RSV-IGIV (1500 mg/kg) to 11 bone marrow transplant recipients after the onset of RSV infection. All but one patient also received ribavirin. Only one patient died in this group, which compares favorably with historical controls given ribavirin therapy alone.

Ghosh and coworkers[243] gave IGIV 500 mg/kg every other day and aerosolized ribavirin to 14 adult bone marrow transplant recipients with RSV upper respiratory tract infection to prevent pneumonia and death. Ten patients resolved their infection, pneumonia developed in four, and two died. Aerosolized human IGIV was of no clinical benefit in the treatment of patients with RSV infection.[562]

Recommendations

Palivizumab is indicated for prevention of RSV infection during the RSV infection season for high-risk premature infants or infants with chronic lung disease.[32] The period of prophylaxis should be individualized, depending on the duration of the local RSV infection season.

Candidates for Prophylaxis. Candidates for prophylaxis are as follows[32]:

1. Infants younger than 24 months with chronic lung disease requiring medical treatment in the 6 months before the start of the RSV infection season. Two seasons of treatment may be required for some infants who require ongoing medical treatment.
2. Premature infants without chronic lung disease who were born before 32 weeks' gestation. For these infants, the major risk factors to consider are gestational age and the chronologic age at the start of RSV season.
3. Infants born at 28 weeks, 6 days' gestation or earlier may benefit from prophylaxis during RSV season whenever that occurs in the first 12 months of life, whereas infants born at 29 to 32 weeks' gestation may benefit most from prophylaxis up to 6 months of age,[32] although decisions should be individualized. Once an infant qualifies for initiation of prophylaxis at the start of RSV season, administration of prophylaxis should continue throughout the season and not stop on the basis of the chronologic age.[32]
4. Premature infants of 32 to 35 weeks' gestation who are 3 months or younger at the start of RSV season, including those born during the RSV season, and have one of the following two risk factors: (1) attends child care in a setting with multiple infants or young toddlers or (2) has one or more older siblings (or other child) younger than 5 years of age living in the household. This prophylaxis should continue until the infant is 3 months of age.[32]
5. Infants under 12 months of age during RSV season with congenital abnormalities of the airway or neuromuscular disease may be considered for immunoprophylaxis if their condition compromises their handling of respiratory secretions.[32]
6. Children younger than 24 months with hemodynamically significant cyanotic or acyanotic heart disease. These criteria include children requiring medication for congestive heart failure, and children with moderate-to-severe pulmonary hypertension. Children with hemodynamically insignificant heart disease are not candidates for palivizumab. This category includes atrial septal defect, small ventricular septal defect, pulmonic stenosis, mild coarctation of the aorta, and patent ductus arteriosus. Children who have had surgical correction and do not require medications for congestive heart failure also are not candidates for prophylaxis. After cardiopulmonary bypass, a postoperative dose of palivizumab can be given to maintain protection because decreased levels of antibody have resulted from cardiopulmonary bypass.[216]
7. Infants who are severely immunocompromised can be considered for prophylaxis, although there are no studies on which to base a recommendation.

Possible Indications. Possible indications for use are as follows:

1. Nosocomial outbreaks. No data exist to support palivizumab use in controlling an RSV outbreak in a hospital setting. However, palivizumab, in addition to implementation of strict isolation practices, has been used in this setting and may be of value in aborting a nosocomial outbreak of RSV infection.[1,171,350,397,622] However, current dosing recommendations for outpatients may not be adequate for some hospitalized premature infants.[752]
2. Patients with cystic fibrosis who are younger than 2 years of age also may be candidates for RSV

prophylaxis, but no data exist on which to base a recommendation.

3. Older high-risk infants who received palivizumab the previous season but remain unwell, are immunocompromised, or have recently undergone a procedure such as transplantation or operation may benefit from a second season of palivizumab. This includes immunodeficient infants receiving IGIV because IGIV has only low titers of RSV antibodies.

Dosage and Administration. Prophylaxis is given monthly from just before the start of the local RSV infection season until the end of the season. Usually, five injections are given from November to March, but starting earlier or extending into April may be required. Thus, it is important to be aware of local outbreak data. If an infant develops RSV infection while receiving prophylaxis, palivizumab should be continued because more than one RSV strain could infect the patient in a single season.[32]

The dose of palivizumab is 15 mg/kg/month given intramuscularly. It is supplied in 50- and 100-mg vials.

As discussed earlier, palivizumab is not indicated for the treatment of RSV infections.

ROTAVIRUS

Several reviews have summarized the role of oral IG in the prevention and treatment of rotavirus infection.[95,178,286,518,726] Its effectiveness varies, in part because of differences in antibody titer in the various products.* Human IG has been used to prevent rotavirus infection; Barnes and colleagues[68] and Pammi and colleagues[518] gave human gammaglobulin orally to low-birth-weight infants in a nursery in which rotavirus was endemic. Patients given human IG had a more attenuated disease than the placebo controls.

Human IG has been infused into the duodenum to treat two children with prolonged rotavirus infection.[275] One patient responded rapidly, but the other had a prolonged course. Losonsky and coworkers[418] gave human IG to three immunodeficient patients and demonstrated that it survived passage of the gastrointestinal tract in an immunologically active form.

Pooled colostrum concentrate from hyperimmunized pregnant cows with high titers to several rotavirus serotypes has been used in several studies.[117] In a controlled study, bovine immune colostrum did not prevent development of symptomatic rotavirus infection in infants, but treated patients had a decrease in the duration of diarrhea.[694] Immune bovine colostrum also was used prophylactically for 2 weeks in 10 infants in a baby care center, with evidence of a protective effect.[196]

A double-blind, placebo-controlled trial of oral lyophilized rotavirus bovine colostrum in Bangladesh showed that a 4-day course decreased diarrhea, the need for oral rehydration, and viral shedding.[588] Mitra and associates[464] also showed that cow colostrum[690] significantly shortened the duration of diarrhea and decreased stool output. Hilpert and colleagues[303] demonstrated that rotavirus colostrum decreased virus excretion in infants with rotavirus diarrhea.

A lactobacillus engineered to express a neutralizing antibody fragment of a llama immunoglobulin (lactobodies) was given orally to experimental animals with rotavirus diarrhea and markedly shortened disease duration, severity, and viral load.[520,700]

A recently licensed vaccine for rotavirus seems safe and effective.[33]

Recommendation

Because rotavirus infection usually is self-limited, no commercial passive antibody product has been developed, although it would be of use in developing countries. The neutralizing titer of human IG probably is not high enough to be consistently beneficial. Oral vaccines may decrease the need for antibody-based therapies.

RUBELLA

IG rarely is used for prevention of rubella because of its uneven efficacy. Early studies suggested some prophylactic benefit. Korns[381] in 1952 showed that one lot of IGIM at a dose of 0.1 mL/lb provided partial protection against the development of epidemic rubella. However, the titers of rubella antibodies varied significantly between lots and did not provided consistent protection.

Studies in epidemic situations have shown that 5 mL of IGIM can prevent development of clinical rubella,[263] but Brody and coworkers[105] showed that an IGIM dose of 0.55 mg/kg resulted in a decreased clinical attack rate but also a high incidence of subclinical infection. Military recruits were protected by a 15-mL dose of IGIM administered before exposure.[309]

Extensive studies on IGIM prophylaxis of rubella conducted by Green[267] and Krugman and Ward[386] did not demonstrate a protective effect of IGIM 0.12 to 0.2 mL/lb. Lundström and coworkers[426] gave 251 exposed pregnant women 4 mL of convalescent rubella IGIM and 28 exposed pregnant women 24 mL of standard IGIM. Rubella developed in 6 of the 251 (2.4%); 3 of these 6 women aborted, and 1 had an infant with probable congenital rubella. None of the 28 women given 24 mL of standard IGIM contracted rubella. Their subsequent study demonstrated that convalescent rubella IGIM given to pregnant women with clinically manifested rubella did not protect against congenital rubella or lessen the probability of fetal damage.[427]

Recommendations

IGIM prophylaxis is not indicated for children and nonpregnant adults exposed to an infected contact because of the mildness of the infection.

IGIM is not recommended for most exposed pregnant women because the clinical syndrome may be masked and congenital rubella not prevented. For exposed pregnant

*References 68, 196, 275, 276, 303, 464, 588.

women who will not consider abortion if rubella develops, IGIM may be of some value in reducing the chance for fetal infection. A dose of 0.55 mL/kg of IGIM given intramuscularly is the recommended dose. However, mothers who have received such prophylaxis after exposure have delivered infants with congenital rubella.[34] Furthermore, the administration of immunoglobulin eliminates the value of IgG antibody testing to detect maternal infection.

VACCINIA, VARIOLA, AND VACCINIA IMMUNOGLOBULIN

Vaccinia virus is closely related antigenically to smallpox (variola) virus, and thus immunity to vaccinia virus through vaccination prevents smallpox.[486] Although smallpox has been eradicated from the world since 1977, the virus nonetheless exists in a few research laboratories and is a potential weapon in biologic warfare.

Vaccination is still given to members of the military, to some health care workers, and to laboratory workers who handle cultures or animals contaminated with vaccinia virus, some recombinant vaccinia viruses, and other orthopoxviruses (e.g., monkeypox or cowpox). Passive immunization occasionally is necessary after laboratory accidents, inadvertent vaccination of high-risk individuals, and exposure of high-risk individuals to a recently vaccinated individual.

Passive immunization against variola was known as early as 1895, when Hlava and Honl[304] showed that schoolchildren could be protected from variola by the injection of 3 to 10 mL of serum from a cowpox-immune calf. At the same time, protective human antibodies developed after vaccination, and passive transmission of these antibodies from mothers to infants was demonstrated.[641] Thereafter, effective prevention of smallpox by well-organized mass vaccination campaigns diminished interest in passive immunization.

Janeway, quoted by Enders,[202] found neutralizing vaccinia antibody in IG in 1944, and Verlinde and Spaander[706] in 1949 found high titers of such antibodies in convalescent IG from recently vaccinated individuals. Gispen and associates[246] in 1956 developed a human vaccinia IG (VIG) that did not interfere with active immunity, and they proposed its use with vaccine as prophylaxis against vaccinia encephalitis. Human VIG is derived from the plasma of vaccinated donors.[140]

The value of human VIG in treating smallpox or disseminated vaccinia is based on the presence of viremia, which leads to secondary dissemination. Administration of neutralizing antibody will prevent or limit the spread of infection and thus modify clinical expression of the disease.

Studies on the efficacy of VIG in treating smallpox and vaccinia complications were initiated by Kempe and colleagues in 1955.[61,364] They used a VIG that was prepared from recently vaccinated donors with a neutralizing titer of 1:256 to 1:512, in contrast to titers of 1:16 or 1:32 in standard IGIM. The households of new admissions to the Madras (India) Smallpox Hospital were visited, and alternate family contacts received VIG 0.2 mL/lb adults and 0.05 to 0.2 mL/lb in children.[364] After 25 days, 8 cases of smallpox developed in 75 contacts not given VIG, and two cases developed in 56 contacts given VIG, a significant difference. A similar, more extensive study disclosed 21 cases of smallpox (4 severe) among 379 contacts serving as controls and 5 cases of smallpox (none severe) among 326 contacts given VIG.[365]

Kempe[363] also reported the results of 300 cases of smallpox vaccination (vaccinia) complications treated with VIGIM, including 62 cases of generalized vaccinia, 132 cases of eczema vaccinatum, 23 cases of vaccinia necrosum, 12 cases of vaccinia encephalitis, and 28 cases of autoinoculation. In addition, VIGIM was given prophylactically to 44 eczematoid children requiring smallpox vaccine (0.6 to 1.2 mL/kg). VIGIM did not affect the course of vaccinia encephalitis. Of 28 patients with autoinoculation who received VIGIM, 27 did well. In the 132 patients with eczema vaccinatum given VIGIM, nine deaths occurred; this 7 percent mortality compares favorably with the usual mortality of 30 to 40 percent with supportive care only. All 62 patients with generalized vaccinia who were given VIGIM did well, although 4 children required a second course.

Of the 23 patients with vaccinia necrosum who received VIGIM, 7 died (30%); however, this disease generally is fatal and immune defects were present in most of these patients.[67] These results strongly supported the efficacy of VIGIM and subsequently were confirmed by studies in Sweden[425] and the United Kingdom.[610]

In 1997, Kesson and coauthors[367] reported a severely immunocompromised patient with progressive vaccinia who had inadvertently received a vaccinia melanoma oncolysate vaccination but was successfully treated with VIGIM and ribavirin. Nanning[480] studied the effect of VIGIM on postvaccinia encephalitis. He gave a placebo or 2 mL of VIG to Dutch military recruits at the time of primary vaccination; three cases of encephalitis occurred in 43,630 vaccinated recruits given VIG, in contrast to 13 cases in 53,044 recruits in the control group. This 77 percent reduction is statistically significant.

Intramuscular Vaccinia Immunoglobulin and Intravenous Vaccinia Immunoglobulin

Two types of VIG are now available, VIGIM (for intramuscular use) and IV-VIG (for intravenous use). IV-VIG was approved in the United States in 2005 for specific indications—treatment of infections that involve accidental implantation in the eye (except for isolated keratitis), mouth, or other hazardous areas; eczema vaccinatum; progressive vaccinia; severe generalized vaccinia; and vaccinia in patients with burns, impetigo, varicella-zoster, poison ivy, or severe eczema. Both VIG preparations are prepared from the plasma of vaccinated donors.

IV-VIG used at a dose of 100 mg/kg results in a more rapid and higher antibody peak than does an injection of VIGIM.[306] The first civilian treated with VIGIV was a woman with vaccinia blepharoconjunctivitis; she also received topical antiviral medication.[311] Another laboratory worker with ocular vaccinia also was treated with a

single dose of VIGIV.[411] IV-VIG is available from CDC under an IND protocol that has guidelines for dosage and administration. The CDC Clinical Consultation Team can be contacted through the Clinicians Information Hotline for VIG requests to treat vaccine-related adverse events.*

Recommendations

Complications of vaccination are the usual indications for VIG. They include accidental or intentional vaccination of a patient with a contraindication to the vaccine, autoinoculation of the eye, eczema vaccinatum, severe generalized vaccinia, and vaccinia necrosum.

The initial dose for VIGIM is 0.6 mL/kg. In adults, the dose must be divided and administered over 24 to 36 hours. Repeated doses can be given at 2- to 3-day intervals for vaccine complications until recovery begins, as evidenced by no new lesions. VIG should be given as soon as possible after diagnosis is established.[8,144]

For unimmunized patients exposed to smallpox, VIGIM in combination with vaccine can be given. A dose of 0.6 mL/kg should be given as soon as possible, preferably within 1 to 3 days.[8,445,694] Current recommendations from the U.S. Army Medical Research Institute of Infectious Diseases suggest that VIGIM may be of value in postexposure prophylaxis of smallpox when it is given within the first week after exposure and concurrently with vaccination. Vaccination alone is recommended for those without contraindications. Both vaccine and VIGIM should be given if more than 1 week has elapsed since exposure occurred.

The current supplies of VIGIM would not permit its routine use in combination with vaccine for bioterrorism exposure,[144] but if additional supplies become available, a VIGIM dose of 0.3 mL/kg in combination with vaccine could be used.

Cidofovir also has been used.[101,102] VIGIM is not indicated for established smallpox, postvaccinial encephalitis, or hypersensitivity and toxic rashes that occur after vaccination. However, the lack of efficacy of VIGIM in the past does not exclude a potential beneficial effect for IV-VIG. The pathogenesis of vaccinial encephalitis is poorly understood and may involve both infection and immune response,[307] and thus VIGIV may be beneficial.

Inadvertent vaccination of a pregnant woman occasionally results in fetal complications, with an estimated fetal vaccinia case rate of 1/10,000 to 100,000 vaccinated pregnant women. Although IV-VIG has not been licensed for this purpose, it can be offered for use as an investigational product. Some investigators suggest use of IV-VIG if it is given within 10 days of vaccination of a pregnant woman.[138,142,481]

In ocular vaccinia, VIGIM is contraindicated for isolated vaccinial keratitis because it may increase corneal scarring,[411] as suggested by animal studies. If additional indications for VIGIM exist, such as conjunctivitis, blepharitis, and eczema vaccinatum, the presence of keratitis is not a contraindication for use of VIGIM. Indeed, scarring can occur from vaccinial keratitis in the absence of VIGIM treatment. The use of IV-VIG has been used in an experimental rabbit model of vaccinia virus keratitis.[16] In this study, the use of IV-VIG neither exacerbated nor ameliorated the keratitis but did not cause the corneal scarring seen with the use of VIGIM. Topical medications such as trifluridine also are recommended.[534]

In summary, VIG products appear to be generally safe with few instances of allergic or adverse reactions. Both the intramuscular and intravenous products are well tolerated, and given that the intravenous administration results in a more favorable pharmacokinetic profile than the intramuscular preparation, this may be the preferred product for significant vaccinia exposures. The recommended dosage of VIGIV (Cangene) for the management of severe complications of smallpox (vaccinia) vaccination (indications listed above) is 6000 U/kg, to be given as soon as symptoms appear.[41] Furthermore, the intravenous product has clinical advantages over the intramuscular product that include absence of mercury, rapid absorption, and more favorable pharmacokinetics.[745]

IV-VIG at a very high dose was used in the treatment of a smallpox vaccinee with undiagnosed acute myelogenous leukemia who developed progressive vaccinia. The total dose given to this patient was 16,740,000 U over 4 days with good resolution.[148] The CDC has developed clinical evaluation tools for smallpox vaccine adverse reactions, which are available on their website.*

REGIONAL VIRUSES

Argentine Hemorrhagic Fever

Junin virus, the etiologic agent of Argentine hemorrhagic fever (AHF), causes a febrile illness with high mortality rates from vascular or neurologic complications.[537] Patients may either improve or have severe hemorrhagic or neurologic manifestations (or both) within the first 2 weeks of illness.[431] Maiztegui and colleagues[431] found that immune plasma given before the ninth day of illness to 91 patients reduced the mortality rate to 1.1 percent in contrast to a mortality rate of 16.5 percent in the 97 patients given normal plasma ($p < .01$). Ten of the patients who received immune plasma relapsed with fever and cerebellar signs after several weeks, as did eight others who were not part of the study. The neurologic relapse was self-limited in all but one patient, who died.

With a case-fatality rate of the illness without treatment between 15 and 30 percent, the use of a live attenuated vaccine has markedly reduced the incidence of AHF.[205] Present specific therapy involves the transfusion of immune plasma with defined doses of neutralizing antibodies during the prodromal phase of illness.[17] However, alternative forms of treatment are called for

*Centers for Disease Control and Prevention Clinical Consultation Team Clinicians Information Hotline: 877-554-4625, http://www.bt.cdc.gov/agent/smallpox/index.asp.

*Centers for Disease Control and Prevention clinical evaluation tools: http://emergency.cdc.gov/agent/smallpox/vaccination/clineval.

because of the current difficulties in early detection of AHF, related to its decrease in incidence, troubles in maintaining adequate stocks of immune plasma, and the absence of effective therapies for severely ill patients that progress to a neurologic-hemorrhagic phase.[205]

Difficulty in obtaining immune plasma, possible neurologic complications of plasma treatment, and lack of efficacy late in the course of the disease have led to the use of ribavirin, despite its limitation late in the disease.[204] An effective, live attenuated viral vaccine currently is in use, with a protective efficacy of 95 percent against AHF.[17,432]

Ebola Infection

Ebola virus, a filovirus, causes severe and often fatal hemorrhagic fever; it has no effective treatment. Kudoyarova-Zubavichene and coworkers[391] reviewed the use of hyperimmune goat or equine serum in the prevention and treatment of Ebola infection. Goat hyperimmune serum protects guinea pigs from experimental infection if it is given less than 24 hours before exposure and provides some benefit if it is given within 72 hours after exposure. This product was used for emergency prophylaxis in four patients exposed by laboratory accidents. Mild infection developed in one definitely exposed patient, but Ebola disease did not develop in the other three patients with questionable exposure. All four patients also received recombinant human INF-α2. Equine serum has protected baboons from low-dose virus challenge but not cynomolgus monkeys from a high-dose virus challenge.[325] Equine serum given to monkeys on the day of infection and 5 days later did not prevent death.[324]

Gupta and coauthors[279] reported that a murine polyclonal immune serum protected 100 percent of normal mice and mice with severe combined immunodeficiency after a lethal challenge. Wilson and colleagues[740] were able to protect mice with monoclonal antibodies to Ebola glycoprotein for up to 2 days after infection. Parren and associates[523] were able to protect guinea pigs by giving a human neutralizing antibody up to 1 hour after infection with Ebola virus. Protection of mice by neutralizing monoclonal antibody before and up to 2 days after virus was also shown.[671] Thus, antibody may be a useful agent in the prevention of Ebola disease. Other human monoclonal antibodies are being developed.[195,438,439,762]

Recommendation

The use of antibody in prevention and treatment of Ebola infection is unproved, but monoclonal antibodies are being developed. Animal studies support a role for antibody in the prevention of Ebola infection.

Tick-Borne Encephalitis

Tick-borne encephalitis is caused by a flavivirus that is endemic in Russia and eastern and central Europe. Several neurologic syndromes are associated with this infection—febrile headache, aseptic meningitis, meningoencephalitis, meningomyeloencephalitis, and postencephalitic syndrome.[191] Meningoencephalitis is the most severe form and can result in death or permanent paresis. Effective vaccines are available[191,278] and have been successful in dramatically lowering the incidence of this disease.[393]

Passive immunization with a hyperimmune human globulin has been used for postexposure prophylaxis in endemic countries, but it may result in antibody-dependent enhancement of infection.[372,717] Arras and colleagues[49] question these case reports in contrast to the large number of doses of passive antibody given. Günther and Hagland[278] contend that hyperimmunoglobulin is not indicated for children younger than 14 years because of concerns that antibody may worsen the disease. The lack of efficacy trials also has led to questioning of the use of this product.[10]

In 1995, von Hedenström and colleagues[714] recommended hyperimmunoglobulin for postexposure prophylaxis in addition to immunization. In a review of 656 patients with tick-borne encephalitis in southern Germany, Kaiser[345] concluded that postexposure prophylaxis with hyperimmunoglobulin is less effective than with vaccine and should be used only when necessary. It is currently believed that vaccine is the best method for disease prevention.

Acknowledgment

We are grateful to Drs. E. Richard Stiehm and Margaret A. Keller, the authors of this chapter in the sixth edition of this book.

OTHER PREVENTIVE CONSIDERATIONS

CHAPTER 246

Public Health Aspects of Infectious Disease Control

Kathleen H. Harriman • Laurene Mascola

PUBLIC HEALTH AND INFECTIOUS DISEASE CLINICIANS

Infectious disease physicians and other clinicians who provide care for patients with known or suspected infectious diseases play an essential role in infectious disease surveillance and are important public health partners. Systematic infectious disease surveillance is critical to inform disease prevention and control efforts and public health practitioners rely on clinicians to report cases of infectious disease.

In addition to the routine reporting of reportable infectious diseases, which is essential for public health surveillance, often the first notification to public health authorities of an unusual case or cluster of disease cases is made by an astute clinician. Only after public health authorities are alerted to an unusual case or cluster of disease cases via reporting by a clinician or by analysis of surveillance data may an investigation take place and any necessary control measures be implemented.

Frontline clinicians play a crucial role in recognizing patients with an unusual constellation of symptoms, symptoms of a disease of public health importance that is rarely seen in the United States, a severe presentation of what is typically a less severe infectious disease, or a severe illness with the hallmarks of infectious disease for which a diagnosis cannot be found. Such cases take on even more importance when the patient has a history of international travel, exposure to exotic animals, or other unusual exposures. When such cases are reported to public health, often they can be evaluated with diagnostic methods that may not be available commercially.

This chapter describes the mutually beneficial collaboration between public health and infectious disease clinicians and includes information on prophylaxis recommendations for some pediatric infectious diseases (Table 246-1).

PUBLIC HEALTH

> *"The success or failure of any government in the final analysis must be measured by the well-being of its citizens. Nothing can be more important to a state than its public health; the state's paramount concern should be the health of its people."*
>
> FRANKLIN DELANO ROOSEVELT

In 1988, the Institute of Medicine in its landmark report *The Future of Public Health*, defined public health as "what we as a society do collectively to assure the conditions in which people can be healthy."[116]

This definition of public health and its overarching core functions (i.e., assessment, policy development, and assurance), which were identified in that report and continue to be used, have led to further descriptions of the essential services of public health (Fig. 246-1).[43]

The scope of public health covers many human health areas, including infectious diseases, chronic diseases, vaccines and immunizations, travelers' health, emergency preparedness and response, environmental health, congenital defects, disabilities, genetics and genomics, health promotion, injury and violence, and workplace safety and health. This chapter will focus on the prevention and control of infectious diseases, although the same principles can be applied to many other health problems.

INFECTIOUS DISEASE SURVEILLANCE

One of the essential services of public health is monitoring the health of the population. Public health surveillance is one method used to monitor the incidence of infectious diseases. The Centers for Disease Control and Prevention (CDC) Working Group on Public Health Surveillance Systems defines public health surveillance as "the ongoing, systematic collection, analysis, interpretation, and dissemination of data about a health-related event for use in public health action to reduce morbidity and mortality and to improve health" and notes that outbreak identification requires "an increase in frequency of disease above the background occurrence of the disease."[40]

The Institute of Medicine's 1988 report highlighted the role and goals of surveillance by recognizing that one of the three core functions of public health—assessment—relies on public health surveillance to identify and describe problems, guide decisions about appropriate actions, and monitor progress.[116]

In 2011, the Council of State and Territorial Epidemiologists stated that the overarching goal of surveillance is "To provide actionable health information to public health staff, government leaders, and the public to guide public health policy and programs."[163]

Uses of infectious disease surveillance data include identifying outbreaks, informing and evaluating disease

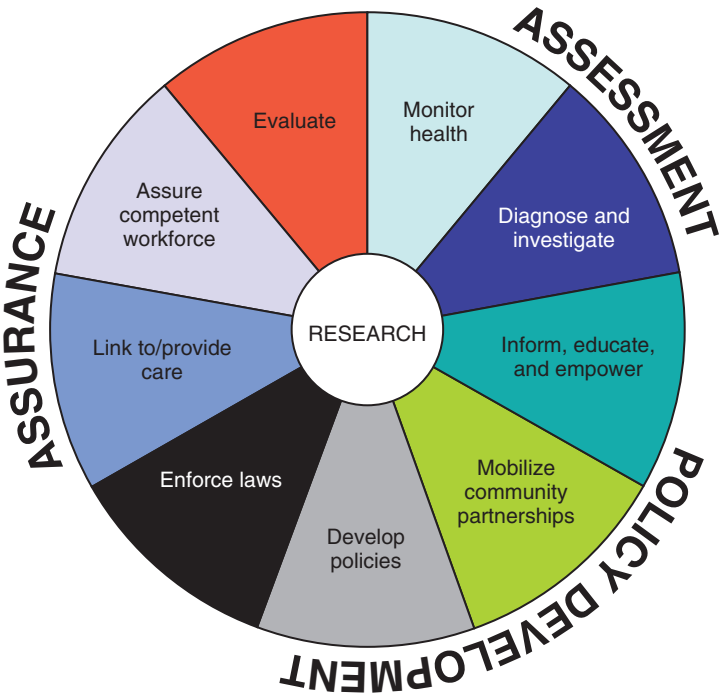

FIGURE 246-1 ■ Core functions of public health and how they relate to the 10 essential services of public health. (From Centers for Disease Control and Prevention. Core functions of public health and how they relate to the 10 essential services. (See companion Expert Consult site for color version.) Available at: http://www.cdc.gov/nceh/ehs/ephli/core_ess.htm.)

prevention and control efforts, determining vaccination strategies and assessing vaccine safety, monitoring antimicrobial resistance, monitoring health care–associated infections, and guiding allocation of resources for disease prevention, control, and treatment programs.

In the United States, the CDC, state, local, and territorial health departments carry out public health functions, including infectious disease surveillance. Public health authorities at the CDC, state, and territorial health departments collaborate in determining which diseases should be nationally notifiable to CDC. Additionally, reporting of specified infectious diseases is required by law in each state. Although health care providers and laboratories are typically designated reporters, state laws vary with regard to the persons who are responsible for reporting, the diseases or conditions that are reportable, and the circumstances under which reporting is to occur.[35,116] Specific information is generally available online or on request from state or local public health agencies.

Although public health is responsible for evaluating and taking action on infectious diseases identified via disease surveillance, unless a report of disease is initiated—by a health care provider, infection preventionist, or laboratory—no information is generated. Without baseline data on the incidence of infectious diseases, an increase or decrease in cases might not be recognized. Timely and accurate public health surveillance data can lead to earlier outbreak detection and more rapid implementation of prevention and control measures. In addition, the impact of intervention activities and other public health activities can be evaluated more accurately, leading to a more rational establishment of priorities.

However, the collection of data without analysis, interpretation, and dissemination of the data is of no value. Public health surveillance system data, obtained by both traditional and nontraditional means, such as syndromic surveillance, can be used for immediate public health action, program planning and evaluation, and formulating research hypotheses.[59,61] When used properly, surveillance data help in directing disease control activities and evaluating their impact.

Incentives to primary reporting sources to maintain good reporting, such as ongoing feedback, are essential for maintaining a useful surveillance system. After surveillance information is analyzed, the results are fed back to the primary reporting source and to others interested in the data. Such feedback serves to sustain interest in the reporting system and thereby maintains the quality of data obtained and continuously updates persons at each level of the surveillance system about the changing patterns of disease occurrence and new strategies for disease prevention and control.

One vehicle for the feedback of national surveillance information is the *Morbidity and Mortality Weekly Report*, which is published by CDC.[47] CDC also publishes periodic summaries of surveillance activities relating to specific diseases. In addition, regular summaries of surveillance activities are published by many state and local health departments as well as the World Health Organization (WHO).[172] Today, most public health agencies have publically accessible websites and most of these summaries are easily available online.

Increased use of automated reporting systems using electronic health records and laboratory results have streamlined the reporting process and improved the completeness and timeliness of surveillance data.[81] In addition, social media is increasingly playing a role in infectious disease surveillance. Public health practitioners use social media to monitor trends and collect data and the public also uses social media to monitor and report

Text continued on p. 3545

TABLE 246-1 **Prophylaxis Against Infectious Diseases in Children**

Disease	Target Group	Value of Prophylaxis	Recommended Drug for Postexposure Prophylaxis	Vaccine for Target Group for Preexposure Prophylaxis	References
Acute glomerulonephritis	Those with group A streptococcal infection in nephritis outbreaks	Proposed	Benzathine penicillin G IM, penicillin V PO, amoxicillin PO *For those allergic to penicillin:* Clindamycin PO, erythromycin PO, clarithromycin, PO azithromycin PO	No	7, 94, 154, 169, 170
Acute rheumatic fever (ARF)	Those with group A streptococcal infection other than impetigo	Shown	Benzathine penicillin G IM, penicillin V PO, amoxicillin PO *For those allergic to penicillin:* Clindamycin PO, erythromycin PO, clarithromycin PO, azithromycin PO The American Heart Association (AHA) no longer recommends prophylaxis for bacterial endocarditis for patients with rheumatic heart disease. For the few patients with rheumatic heart disease in whom prophylaxis is still recommended (e.g., people with prosthetic valves), current AHA recommendations should be followed using an agent other than a penicillin.	No	7, 155, 175
	Those with well-documented history of ARF (including cases that manifested only with Sydenham chorea) and those who have documented evidence of rheumatic heart disease	Shown	Benzathine penicillin G IM, Penicillin V PO, Sulfadiazine/sulfisoxazole PO *For those allergic to penicillin:* Erythromycin PO, azithromycin PO, continuous long-term prophylaxis should be initiated as soon as the diagnosis of ARF or rheumatic heart disease is made.		
Poststreptococcal–reactive arthritis (PSRA)	Those with previous PSRA	Proposed	Patients should be observed carefully for 1 to 2 years for carditis. Some experts recommend secondary prophylaxis for these patients during the observation period. If carditis occurs, the patient should be considered to have had ARF, and secondary ARF prophylaxis should be continued.	No	7, 167
Anthrax	Those exposed in an intentional release	Proposed	When organism susceptibility is unknown, ciprofloxacin PO and doxycycline PO are equivalent first-line antimicrobial agents. Levofloxacin PO is a second-line antimicrobial agent for people ≥6 months of age. When susceptibility to penicillin has been confirmed, amoxicillin PO should be used.	Yes (adults) Anthrax Vaccine Adsorbed is not licensed for use in pediatric populations and has not been studied in children.	3, 57, 58, 177

Chlamydia trachomatis	Infants born to infected women		Prophylactic antimicrobial treatment is not indicated, because the efficacy of such treatment is unknown. Infants should be monitored to ensure treatment if infection develops. If adequate follow-up cannot be ensured, some experts recommend that preemptive therapy be considered. Topical antibiotic therapy alone is inadequate.	No	4, 176
	Sexual contacts of confirmed cases	Shown	Azithromycin PO, doxycycline PO *Alternatives:* Erythromycin PO, erythromycin ethylsuccinate PO, ofloxacin PO, levofloxacin PO		
Cholera	Close contacts	Rarely indicated	Tetracycline PO, doxycycline PO, trimethoprim-sulfamethoxazole PO, furazolidone PO, erythromycin PO	Yes	108, 174
Diphtheria	Close contacts	Shown	Erythromycin PO, Benzathine, penicillin G IM	Yes	5, 56, 83, 93, 141
Gonorrhea	Infants born to infected women	Shown	Erythromycin ophthalmic ointment *and* ceftriaxone IV or IM	No	6
	Sexual contacts of confirmed cases	Shown	Combination therapy with ceftriaxone IM and either azithromycin PO as a single dose or doxycycline PO twice daily for 7 days		68, 86, 176
Haemophilus influenzae type b	Index case Household contacts when at least 1 contact <48 months of age is partially or unimmunized or is immunocompromised child of any age or vaccination status Childcare and preschool contacts when ≥2 cases have occurred <60 days when partially or unimmunized children are present	Shown	Cefotaxime or ceftriaxone for treatment and eradication of carriage (index case). If other antimicrobial used for treatment, rifampin should be used to eradicate carriage. Rifampin (contacts)	Yes	1, 9, 133
Hepatitis A infection	Close contacts	Shown	Hepatitis A vaccine immunoglobulin IM	Yes	10, 100
Hepatitis B (HBV) infection	Infants born to infected women Those who have been exposed to HBV-containing blood or other potentially infectious materials	Shown	Hepatitis B vaccine, hepatitis B immunoglobulin IM	Yes	11, 140

Continued on following page

TABLE 246-1 **Prophylaxis Against Infectious Diseases in Children** (Continued)

Disease	Target Group	Value of Prophylaxis	Recommended Drug for Postexposure Prophylaxis	Vaccine for Target Group for Preexposure Prophylaxis	References
Human Immunodeficiency Virus (HIV) infection	Infants born to infected women Those who have been exposed to HIV-containing blood or other potentially infectious materials	Shown	Consult a specialist or contact the National HIV/AIDS Clinician's Perinatal HIV Hotline at: 888-448-8765 Consult a specialist or contact the National HIV/AIDS Clinician's Post-Exposure Prophylaxis Hotline at: 888-448-4911	No	12, 145, 162
Influenza	Those at high risk for influenza complications and institutional residents	Shown	Oseltamivir PO, zanamivir PO	Yes	13, 99
Leprosy	Household contacts (not in United States)			Yes (bacilli Calmette-Guérin) BCG vaccine and heat killed leprosy vaccine Neither vaccine is recommended for household contacts of people with leprosy in the United States	14, 156
Malaria	Travelers to malarious areas	Shown	Specifics are highly detailed. Consult CDC at http://www.cdc.gov/malaria/ or the CDC Malaria Hotline at 770-488-7788)	No	15, 31, 134, 142
Measles	Susceptible close contacts	Shown	MMR vaccine immunoglobulin IM	Yes	16, 87, 95, 122, 160, 164
Meningococcal disease	Close contacts, index case	Shown	Rifampin* PO, ceftriaxone IM Ciprofloxacin* PO, azithromycin PO If ceftriaxone or cefotaxime not used for treatment, should receive prophylaxis as earlier to eradicate carriage. *Not recommended for pregnant women.	Yes for serogroups A, C, Y, and W135 in the United States	17, 34, 70, 84, 110, 112, 179
Methicillin-resistant *Staphylococcus aureus* infection	Those with recurrent skin or soft tissue infections despite optimizing wound care and hygiene measures Close contacts in settings with ongoing transmission despite optimizing wound care and hygiene measures	Proposed	Mupirocin (topical) with skin antiseptic solution (e.g., chlorhexidine) or dilute bleach baths. An oral antimicrobial to which the strain is susceptible may be used in combination with rifampin if infections recur despite use of the measures described earlier.		23, 130

Ophthalmia neonatorum (chlamydia and gonorrhea)			Three agents are licensed for neonatal ocular prophylaxis in the United States: 1% silver nitrate solution, 0.5% erythromycin ointment, and 1% tetracycline ophthalmic ointment or suspension. However, only 0.5% erythromycin ointment is available commercially in the United States. Although all 3 agents are effective against gonococcus, none prevents transmission of *C. trachomatis* from mother to infant.		20, 176
Pertussis	Household and other close contacts, child care contacts, irrespective of vaccination status Some states recommend prioritizing prophylaxis to high risk close contacts, i.e., infants <1 yr of age, pregnant women, and those with infant contact	Shown	Azithromycin PO, Erythromycin PO, Clarithromycin PO, Trimethoprim-sulfamethoxazole PO	Yes	2, 18, 56, 83, 105, 107
Plague	Those exposed to a known or suspected plague source, such as *Yersinia pestis*–infected fleas or infectious tissues Close contacts of pneumonic cases People exposed via an intentional release	Proposed	Doxycycline PO, ciprofloxacin PO *For children <8 years of age:* Tetracycline PO, chloramphenicol PO, and trimethoprim-sulfamethoxazole PO are also alternative drugs. Ciprofloxacin PO, doxycycline PO, amoxicillin PO	Not in United States	19, 115
Rabies	Those potentially exposed to rabies virus via a break in the skin caused by the teeth of a rabid animal or by contamination of scratches, abrasions, or mucous membranes with saliva or other potentially infectious material, such as neural tissue, from a rabid animal		Rabies vaccine, Rabies immunoglobulin IM	Yes	21, 136, 157
Streptococcal infection, invasive Group A disease	Household contacts		A clearly effective regimen has not been identified to justify routine chemoprophylaxis of all household contacts. Clinicians may choose to offer targeted prophylaxis to household contacts who are ≥65 years of age or who are members of other high-risk populations (e.g., people with HIV infection, varicella, or diabetes mellitus).		7, 166

Continued on following page

TABLE 246-1 **Prophylaxis Against Infectious Diseases in Children** (Continued)

Disease	Target Group	Value of Prophylaxis	Recommended Drug for Postexposure Prophylaxis	Vaccine for Target Group for Preexposure Prophylaxis	References
Streptococcal infection, group B (GBS)	Women with group B streptococci isolated from urine during current pregnancy or who have had a previous infant with GBS disease* If GBS status is not known at onset of labor or rupture of membranes, intrapartum prophylaxis should be administered to all women with gestation <37 wk, duration of membrane rupture ≥18 hours, or intrapartum temperature of ≥38.0°C (100.4°F) *Not recommended for cesarean deliveries performed before labor onset in women with intact amniotic membranes.	Shown	*Intrapartum:* Penicillin G IV (ampicillin) IV is an acceptable alternative). *For those allergic to penicillin:* Without a history of anaphylaxis: Cefazolin IV With a history of anaphylaxis: Clindamycin IV if organism susceptible, Vancomycin IV if organism not susceptible or unknown. Prophylaxis for infants born to mothers who have received adequate intrapartum prophylaxis is not recommended.		8, 28, 85
Syphilis	Infants born to infected women Those exposed <90 days before the diagnosis of primary, secondary, or early latent syphilis in a sex partner Those exposed >90 days before the diagnosis of primary, secondary, or early latent syphilis in a sex partner if serologic test results are not available immediately and the opportunity for follow-up is uncertain	Shown	Consult an expert. See CDC recommendations[116] Benzathine penicillin G IM	No	24, 176
Tuberculosis	Close contacts with impaired immunity (e.g., HIV infection) and all contacts <4 years of age even if tuberculin skin test or interferon-γ release assay is negative	Shown	Isoniazid PO	Yes. BCG indications in the United States	25, 51, 54, 63
Varicella	Susceptible close contacts at high risk for severe disease	Shown	Varicella vaccine, varicella-zoster, immunoglobulin (VariZIG)	Yes	26, 137
Yaws	Close contacts	Shown	Azithromycin PO Benzathine penicillin G IM (use when azithromycin is not available or when the patient cannot be treated with azithromycin)	No	143, 173, 142a

IM, Intramuscularly; *IV*, intravenously; *PO*, orally.

disease. The use of social media and online resources will continue to enhance public health surveillance.

HOW PUBLIC HEALTH CAN ASSIST CLINICIANS

Clinicians can contact public health agencies for consultation when they encounter patients who may have infectious diseases with known, unknown, or unclear etiologies. When a clinician encounters a patient who has an unusual or severe presentation of what appears to be an infectious disease or becomes aware of a cluster of patients with similar symptoms, public health may be able to assist with determining a diagnosis.

Point-of-care bi-directional communication between public health practitioners and clinicians can facilitate clinical decision making based on the most current public health information. For example, public health practitioners can inform clinicians about infectious diseases known to be circulating in the area of the patient's residence and about infectious diseases patients may have been exposed to during travel. Public health practitioners can also provide recommendations for treatment and isolation of infected patients and postexposure prophylaxis for their contacts, including first responders such as emergency medical services personnel.

In addition, public health laboratories can be extremely helpful to clinicians. Although clinical laboratories provide excellent service for routine testing, they may not be able to test for more obscure pathogens. If an unusual disease is suspected, public health laboratories can perform testing for an array of possible agents, including biologic threats. Public health practitioners and laboratories also may be able to assist clinicians in establishing a diagnosis when the differential diagnosis contains several possible infectious disease entities with similar clinical presentations. New infectious disease diagnostic technologies will continue to be developed and are likely to be initially available only at public health laboratories.

Public health laboratories can often also detect more common pathogens such as *Neisseria meningitidis* or *Streptococcus pneumoniae* in clinical specimens that have not grown in culture in clinical laboratories by using nucleic acid–based assays such as polymerase chain reaction (PCR) because the sensitivity of the PCR test is not affected by prior antibiotic treatment.[148] Public health laboratories may also perform PCR testing for other diseases such as measles, which can be diagnostically challenging in an era of low incidence.

In addition to identifying disease causing pathogens, public health laboratories are able to use molecular methods to perform strain typing that further characterizes pathogens and may identify novel strain types. Such testing may also detect new agents and identify outbreaks. A public health laboratory first identified 2009 pandemic H1N1 influenza A.

Advancement in laboratory methods has also enhanced the usefulness of surveillance data in outbreak detection by linking bacterial isolates obtained from geographically scattered cases. CDC coordinates PulseNet,[42] a national network of public health and food regulatory agency laboratories that perform standardized molecular subtyping (genetic fingerprinting) on foodborne bacteria by pulsed-field gel electrophoresis (PFGE).

PFGE testing can be used to distinguish strains of organisms such as *Escherichia coli* O157:H7, *Salmonella*, *Shigella*, *Listeria*, or *Campylobacter* at the DNA level. DNA "fingerprints," or patterns, are submitted electronically to a dynamic database at CDC. This database is available on demand to participants, which allows for rapid comparison of the patterns and identification of clusters, which can lead to identification and removal of contaminated food products from the homes of consumers thereby preventing further disease.

Testing methods such as such as antigen-based tests and nucleic acid–based assays that do not depend on culture and produce no isolate have become increasingly common, particularly for enteric bacterial pathogens. The use of these tests has implications for public health surveillance. Although such tests may identify more cases, they may also produce large numbers of false positive results if their specificity is low and they are used in low-prevalence populations. In addition, such tests do not allow public health practitioners to monitor microbiologic characteristics such as antimicrobial resistance or to use other isolate characteristics such as subtype and susceptibility profile that are used in addition to other data to attribute illness to specific sources. Therefore, some isolate-based monitoring will remain necessary, although it may be possible to establish sentinel sites to obtain isolates.[89]

Although the increasing availability of home tests for reportable infectious diseases such as human immunodeficiency virus, hepatitis B, and hepatitis C will make such tests more accessible to the public, surveillance activities for diseases that can be diagnosed in this manner will be hampered and the impact of this is difficult to predict.

OUTBREAK INVESTIGATION

When faced with an unusual case or cluster of cases that may be of public health concern, public health authorities conduct an investigation in an attempt to determine or confirm a diagnosis, describe the scope of the problem, and, if unknown, identify a cause. Front-line clinicians may be called upon to assist in such investigations.

When investigating a possible outbreak, a useful approach is for investigators to address the inquiry systematically using CDC's 10-step method[51]:

Prepare for Fieldwork

The following are the steps in preparing for fieldwork:

1. Establish the existence of an outbreak
2. Verify the diagnosis
3. Define and identify cases
4. Describe and orient the data in terms of time, place, and person
5. Develop hypotheses
6. Evaluate hypotheses
7. Refine hypotheses and carry out additional studies

8. Implement control and prevention measures
9. Communicate findings

Several exercises illustrating these principles, including communicable and noncommunicable disease outbreaks, can be found at the CDC's training site for epidemic intelligence service officers.[44]

PUBLIC HEALTH PREVENTION AND CONTROL MEASURES

Once an unusual case or cluster of cases is recognized and an investigation has occurred, many tools are available for public health intervention, if it is indicated. Two important interventions, immunization and the treatment of individual patients, are not considered in this chapter because they are addressed at length elsewhere in this book. Public health tools that are discussed here include isolation, quarantine, and preexposure and postexposure prophylaxis.

Other public health tools that are not discussed here but are also relevant to the control of infectious diseases include modifications to human behaviors that affect exposure to infectious diseases such as sexual behavior and injection drug use, water and food sanitation, food preparation methods, and so on.

Additionally, various prevention and control measures can be applied to animals, such as vaccination and treatment or prophylaxis, that decrease their risk for spreading diseases to humans.[121] Finally, prevention and control measures can be applied to the environment, such as proper disposal of waste, vector control, and appropriate design and proper maintenance of buildings and or other equipment that can reduce opportunities for disease transmission. An example of such a control measure would include proper maintenance of spas or cooling towers to prevent *Legionella* transmission.

Isolation

Isolation is the separation of persons who have a specific infectious illness from those who are healthy and the restriction of their movement to stop the spread of that illness during the period of communicability.[49] Indications for isolation of patients with infectious diseases have changed greatly in this century with increasing knowledge about modes of transmission and with antimicrobial therapy, which rapidly renders patients with many diseases noninfectious. The American Academy of Pediatrics (AAP) *Red Book: Report of the Committee on Infectious Diseases* is an excellent resource for information about isolation recommendations.[22]

Quarantine

In addition to containing the spread of communicable illnesses through isolation, another less commonly used control measure is quarantine. Quarantine is the separation and restriction of movement of persons who, while not yet ill, have been exposed to an infectious agent and therefore may become infectious.[45,46] When quarantine is used it is imposed for a period equal to the longest usual incubation period of the disease.

The history and practice of quarantine began as early as the 14th century in Italy to control plague by requiring ships arriving in Venice from infected ports to anchor for 40 days before landing.[46] The Italian word, *quaranta*, meaning 40, turned into the commonly used word *quarantine*.

In recent years, health departments in the United States have rarely implemented quarantine. However, it was used during the 2003 severe acute respiratory syndrome (SARS) outbreak and is occasionally used for susceptible persons who have been exposed to measles and did not receive postexposure prophylaxis.

Preexposure and Postexposure Prophylaxis

The word *prophylaxis* is used in this section to describe the use of antimicrobial or immunologic agents to prevent infection before or after exposure to an infectious disease. The decision to initiate prophylaxis and the choice and dosage of agents require careful consideration of both the child's clinical status and the epidemiologic factors that may place the child at risk for acquiring the disease. Public health authorities should be notified of cases and exposures of reportable infectious diseases; they may need to conduct an investigation to ensure that all exposed persons have been identified and, when necessary, treated or placed under observation. In addition, they often can provide useful additional information on recommended prophylaxis regimens.

A summary of several diseases for which prophylaxis may be administered to children is given in Table 246-1. Some special situations, such as prophylaxis for immunodeficient children and perioperative prophylaxis, are omitted from the discussion. For a more detailed discussion of the use of prophylaxis in prevention of infectious disease, the regularly updated AAP *Red Book: Report of the Committee on Infectious Diseases* should be consulted.[22]

COMMON PATTERNS OF DISEASE SPREAD

Animal to Person

Many infectious diseases are transmitted from animals to humans (zoonoses). Of all emerging diseases in the 20th and 21st century, over 75 percent are zoonotic in origin.[104] Clinicians who routinely inquire about animal contacts as part of the clinical and epidemiologic history of an ill patient frequently find valuable clues to an obscure diagnosis.

Details of the clinical manifestations, differential diagnosis, and treatment of zoonoses are found in the appropriate chapters elsewhere in this book. For a complete description of the circumstances under which each agent is spread from animal to person, consult a textbook of zoonoses. Often emerging infectious diseases in humans, such as SARS, are found to have an animal reservoir.[124]

Person-to-Person

As members of groups—including families, school, camp, childcare center, and religious organizations—children are at risk for acquiring or spreading infectious agents that are transmitted from person-to-person. Knowledge of the typical patterns of spread can be useful in planning surveillance or in designing control measures. For example, recognition that diarrhea commonly results from person-to-person spread in childcare centers and that it can indicate inadequate hygienic practices may justify specific surveillance for diarrhea in that setting. Documentation of secondary cases in various categories of contacts of cases of meningococcal disease permits focusing the delivery of chemoprophylaxis on high-risk groups.

In this section, disease transmission in the household, childcare centers and schools is briefly discussed. The important areas of disease transmission in childcare centers and hospitals are discussed in separate chapters in more depth. Maternal transmission of specific infections to the fetus or neonate is also reviewed elsewhere in this book. Spread of enteric diseases within institutions for the developmentally disabled is recognized widely as an important problem, but it does not pertain directly to the practice of most clinicians and is not discussed in this chapter.

EXAMPLES OF EXPOSURE SOURCES

Contaminated Food

Many foods have been shown to be the vehicle of transmission in outbreaks caused by a wide range of bacteria, viruses, and parasites, in addition to many naturally occurring toxins and human-made chemicals. Inherent contamination of meat, poultry, and eggs with *Salmonella*, *Yersinia*, shiga toxin–producing *E. coli*, listeria, and other pathogens, as well as deficiencies in food storage and preparation and ingestion of raw or improperly cooked animal products in both eating establishments and the home still contribute to outbreaks and sporadic cases of gastrointestinal infectious diseases.[80,102,145,150] In addition, practices with known risks such as drinking unpasteurized milk can result in infection.[64,75]

Outbreaks of infection and secondary hemolytic-uremic syndrome resulting from infection with shiga toxin–producing *E. coli* strains such as O157:H7 and O104:H4 have been related to juice,[117,168] lettuce,[103] spinach,[66] sprouts,[39,171] and unpasteurized milk[64,106] and other food items. In addition, new problems can result from changes in the food industry and in patterns of food consumption.[33,147] In recent years, several large outbreaks of salmonellosis have been associated with the widespread distribution of fresh produce, a previously rare vehicle of salmonella transmission.[33]

CDC publishes a "Foodborne Outbreak Online Database"[78] and although the number of outbreaks reported to public health authorities represents only a small fraction of those that occur, these reports can provide important insight into the epidemiology of foodborne disease.

Clinicians must work in conjunction with public health authorities by confirming diagnoses through appropriate diagnostic methods and promptly reporting findings or suspicions so that foodborne outbreaks can be recognized in a timely fashion to control and prevent these illnesses most effectively.[49]

Recreational Water

An increasingly important problem is the occurrence of outbreaks of waterborne disease associated with recreational water use, such as for swimming or wading,[32,82,153] hot tubs and spas,[114,123] water parks,[72] and decorative fountains.[109] Diseases transmitted in this manner include shigellosis, cryptosporidiosis, norovirus gastroenteritis, viral conjunctivitis, giardiasis, legionellosis, enterohemorrhagic *E. coli* O157:H7, and *Pseudomonas* dermatitis ("hot tub folliculitis").[69,178]

Deaths may occur, especially with cases of primary amebic meningoencephalitis caused by any of several free-living amebae in persons who had recently been swimming, typically in warm, stagnant water.[74,131] Of note, a case of primary amebic meningoencephalitis caused by *Naegleria fowleri* was recently reported in an area at much higher latitude than previous cases.[119]

Unpasteurized Milk

Unpasteurized milk has been demonstrated as the vehicle of transmission in outbreaks of brucellosis, tuberculosis, and diphtheria, as well as outbreaks of diseases caused by group A streptococci, *Salmonella*, *Shigella*, *Campylobacter*, listeria, *Yersinia enterocolitica*, and staphylococcal toxin.[118,126] Exposure to unpasteurized milk should be rare in the United States. Unfortunately, the use of raw milk as a "health food" continues to account for outbreaks of disease, particularly outbreaks caused by *E. coli* O157:H7, *Salmonella*, and *Campylobacter*.[64,106,126,149] In addition, children sometimes drink raw milk while visiting dairy farms on school field trips, during other youth activities, or during travel to other countries, which puts them at risk for infectious diarrhea and shiga toxin–producing *E. coli*–related renal failure.

Bioterrorism and Natural Disasters

Unfortunately, an important responsibility of public health authorities is to help prepare the nation and clinicians for the possibility of biologic, radiologic, or chemical terrorism and natural disasters. Children have special vulnerabilities to biologic terrorism and chemical agents because of their unique physiology and the limited availability of age-appropriate and weight-appropriate antidotes and treatment.[138,151] Also, clinicians' unfamiliarity with presenting clinical syndromes from either biologic or chemical exposures can delay appropriate diagnosis and treatment.[88,151,159]

Another issue is that the Strategic National Stockpile, a national repository of antimicrobial agents, chemical antidotes, antitoxins, and other life-support medications and equipment, can only stockpile U.S. Food and Drug Administration (FDA)-licensed items and only for their

FDA-approved indications.[139] Often FDA indications for antimicrobial and other therapeutic agents for children after biologic terrorist agent release are lacking, causing the stockpile to be deficient in certain therapeutic agents for children.

Terrorism preparedness is a unique and hopefully rare component of general emergency and disaster preparedness. However, natural disasters are more common and infections that are typically rare in the United States can result from compromised personal hygiene, wounds and injuries, contaminated food and water, and exposure to insect vectors. Prompt recognition and appropriate management by clinicians of unusual diseases is critical during and after disaster situations.

COMMON DISEASE TRANSMISSION SETTINGS

Households

Spread of disease agents in the family can be considered in two stages: introduction of the agent into the family, usually by a single member, and spread to other family members. Spread to other members can be described in terms of rapidity and intensity, the latter commonly measured by the secondary infection rate (or secondary attack rate), which is defined as the proportion of the contacts of the index carrier or index case who become infected (or ill) in a given interval after exposure. The secondary infection rate varies from agent to agent and may be affected by the age and sex of the introducer; the size of the family; crowding; the age of household contacts; previous immunity; and interventions attempted, including vaccination, isolation, treatment, and prophylaxis. The ratio of the secondary attack rate to the incidence of disease in the community is a measure of the importance of the family as a focus of disease.[41,101]

Childcare Centers

It is well known that infectious disease agents are easily transmitted among children in childcare centers and that outbreaks occur in these settings.[37,111,125] Interventions that have proved valuable for reducing infections within childcare centers include formal written policies for infection prevention and control within the childcare center, formal education of childcare center staff concerning infection prevention practices, good hand hygiene by both staff and children, appropriate cleaning of contaminated surfaces, separation of food preparation and diaper changing areas, exclusion of certain ill children, cohorting ill children when exclusion is not possible, ensuring adequate age-appropriate immunization of childcare attendees and staff, and optimal ratios of children to staff.[36]

Schools

Typically, infectious disease spread in schools is less than that in families and childcare centers. However, schools may serve to spread infection from family to family. Settings that result in a greater level of person-to-person contact than found in typical classroom settings, such as participation in school sports[29,76] or attendance at boarding schools, summer camps, and college dormitories also can result in more efficient transmission of disease.[113,158,161] In recent years, measles, mumps, influenza, meningococcal disease, norovirus, and methicillin-resistant *Staphylococcus aureus* outbreaks have occurred in these settings.*

HEALTH INFORMATION FOR INTERNATIONAL TRAVEL

International travel, whether by child or adult, necessitates preparation beforehand to obtain the proper immunizations and contingency plans for the possibility of encountering unsanitary food or water during the travel.[98,120,135,146] Illnesses acquired abroad may not be manifested until after returning home, with consequent diagnostic difficulty. Clinicians should query parents regarding travel when children have unusual symptoms or febrile rash illnesses.

Active and passive immunization are covered elsewhere in this book, and updated travel-related immunization information is available at CDC's traveler's health website.[52,98,135,146] Disease-specific information for travelers and clinicians is available in CDC's "Yellow Book" at that website.[52]

In addition, travel notices are available that can alert travelers and clinicians to infectious disease outbreaks occurring throughout the world. For example, during the period 2003 to 2009, substantial progress was made toward the goal of measles elimination in Europe. However, in late 2009 through 2011, measles virus transmission increased as a result of declining immunization rates and outbreaks in Europe became widespread and cases are still occurring. Infants traveling to parts of the world where measles is circulating should be vaccinated as young as 6 months of age.†

Safe water may be found in many hotels in large cities throughout the world, but only water from adequately chlorinated sources can be considered truly safe. Where chlorinated water is not available, canned or bottled carbonated beverages and beverages made from boiled water or that contain alcohol may be safe; however, an outbreak caused by commercially bottled water contaminated by non-O1 *Vibrio cholerae* has been described.[53] Ice made from untreated water may contaminate an otherwise safe beverage, either directly or by leaving contaminated water on the outside of the container. The CDC has prepared guidance on preparation and storage of safe water that can be found online.[48]

Food should also be selected carefully. In areas of the world where hygiene and sanitation are poor, travelers should avoid intake of salads, uncooked vegetables, unpasteurized milk, and milk products such as cheese and should eat only fruits and vegetables that can be peeled by the traveler or have been cooked and are still hot. In addition to a recommendation that all children receive hepatitis A vaccine, persons who are traveling to

*References 67, 71, 73, 77, 84, 127.
†References 55, 79, 98, 135, 146, 165.

countries with high or intermediate levels of endemic hepatitis A infection are also recommended to receive hepatitis A vaccine before departure.[100]

Children younger than 2 years of age have a high risk for acquiring traveler's diarrhea.[30,132,152] Traveler's diarrhea is caused by several bacterial pathogens, including *E. coli*, *Shigella*, *Campylobacter*, *Salmonella*, *Aeromonas*, *Plesiomonas*, and noncholera vibrios. Noroviruses are also an important cause of morbidity among travelers. Recently, genetic risk factors associated with susceptibility to specific pathogens have been identified.[92] Immediate medical attention should be sought for an infant or child with blood or mucus in the stool, fever with rigors, or persistent vomiting or diarrhea with dehydration.

Because infants and small children are especially at risk for becoming dehydrated, parents need to be aware of the signs of dehydration and be prepared to use oral rehydration solutions containing appropriate concentrations or electrolytes as a preventive measure while medical attention is being obtained. WHO oral rehydration solutions are widely available at stores and pharmacies in most developing countries.

For more information on traveler's diarrhea, including antimicrobial treatment and oral rehydration therapy, please see the CDC Yellow Book.[52]

VECTORBORNE DISEASE

Vectors such as mosquitos and ticks can transmit infectious diseases. Examples of tick-borne diseases in the United States include anaplasmosis, babesiosis, ehrlichiosis, Lyme disease, Rocky Mountain spotted fever, tick-borne relapsing fever, tick paralysis, and tularemia. Mosquito-borne diseases that have been found in the United States include West Nile virus infection, eastern equine encephalitis, La Crosse encephalitis, St. Louis encephalitis, and western equine encephalitis. Malaria has rarely been transmitted in the United States,[65] but several dengue outbreaks have been detected in the United States since 1980, including seven outbreaks in southern Texas along the U.S.-Mexico border, one outbreak in Hawaii in 2001, and two outbreaks in southern Florida in 2009 and 2010.[38] Other vectorborne infections that can be carried back from foreign travel include chikungunya, Rift Valley fever, yellow fever, and many others. In addition, fleas can spread endemic or murine typhus, plague, and cat-scratch fever, and body lice can spread epidemic typhus, relapsing fever, and trench fever.[90,91,97,128]

The CDC has excellent online resources for vectorborne diseases,[87] and local and state public health practitioners can provide clinicians with information on vectorborne diseases in the geographic regions they serve and other regions where patients may have traveled. In addition, public health laboratories may be able to assist in establishing a diagnosis.

VECTOR PROTECTION

Personal protection against vectors such as mosquitos and ticks includes avoiding vector-infested areas, wearing protective clothing, using insect repellents applied to skin or clothing, and frequently inspecting for and promptly removing attached ticks. These individual preventive measures can be practiced in any circumstance where exposure to infected mosquitos or ticks may occur.[129]

Of the active ingredients currently registered with the U.S. Environmental Protection Agency (EPA), the CDC reports that DEET (N,N-diethyl-m-toluamide) and picaridin (KBR 3023) demonstrated a higher degree of efficacy and that products containing these active ingredients typically provide longer-lasting protection than others.[50] Another effective product is IR3535 (3-[N-butyl-N-acetyl]-aminoproprionic acid, ethyl ester).

Oil of lemon eucalyptus and its synthetic equivalent *p*-menthane 3,8-diol, a plant-based repellent, also is registered with the EPA. When oil of lemon eucalyptus was tested against mosquitoes in two recent scientific publications in the United States, it provided protection similar to that of repellents with low concentrations of DEET. Oil of lemon eucalyptus products should NOT be used in children younger than 3 years of age.

The EPA characterizes the active ingredients DEET and picaridin as "conventional repellents" and oil of lemon eucalyptus as a "biopesticide repellent," which is derived from natural materials. More information on repellent active ingredients is available online at the EPA website.[96]

Although no definitive studies exist in the scientific literature about what concentration of DEET is safe for children, no serious illness has been linked to the use of DEET in children when used according to manufacturer's recommendations.

The American Academy of Pediatrics has supported the 2001 EPA recommendation that appropriate use of DEET at concentrations of up to 30 percent pose no significant risk to children or adults but that DEET should not be used in children younger than 2 months of age because of increased skin permeability.[27] The CDC currently recommends DEET at concentrations up to 50 percent for both adults and children older than 2 months of age.

Certain products containing permethrin are recommended for use on clothing, shoes, bed nets, and camping gear and are registered with EPA for this use. Permethrin is highly effective as an insecticide and a repellent. Permethrin-treated clothing repels and kills ticks, mosquitoes, and other arthropods and retains this effect after repeated laundering.

PROPHYLAXIS AGAINST INFECTIOUS DISEASES IN CHILDREN

Many infectious diseases can be prevented by preexposure or postexposure prophylaxis. Table 246-1 describes prophylaxis recommendations for selected infectious diseases in children.

CHAPTER 247

Infections in Child Care Environments

Sheryl L. Henderson • Ellen R. Wald

Of the estimated 20 million children younger than 5 years identified in the 2010 U.S. Census, approximately 12 million (60%) were in some type of regular child care arrangement at least once a week. Approximately half of these received care provided by parents or relatives. Of the remainder, nearly 4.5 million (23%) preschool-age children were cared for in an out-of-home organized child care facility (such as a daycare, nursery, or preschool), and 2.4 million (12%) had care provided by a nonrelative either in their own home or a family daycare setting.[229]

The term *child care* is used to describe a variety of different options for the supervision of children in the absence of a parent or legal guardian. Types of child care include large child care centers housed in nonresidential settings that provide care for at least seven children in one location (included here are situations in which the parent's employer is the sponsor of the child care center, frequently at the site of employment, and also preschool and nursery schools in which child care is provided in a structured, primarily educational setting); child care homes in which care is provided in a residential setting for six or fewer children; before- and after-school care designed to bridge the gap between organized schools (e.g., preschool or public or private school) and parental departure for or return from work; and cooperatives in which child care is rendered by parents who alternate in caring for their own children as well as other enrolled children.

The quality of care provided to children attending various child care facilities varies widely. Although child care centers are licensed in most states, only 23 percent of children with regular child care arrangements attend licensed facilities.[229] State regulations vary from state to state; some are lenient in setting suggested ratios for staff to child, and some have no regulations governing group size. Even if impeccable regulations and well-trained caregivers were available, the regulations would not protect the majority of children who are in unlicensed facilities.

FACTORS AFFECTING TRANSMISSION OF INFECTIOUS AGENTS

Several studies have demonstrated increased numbers of infections in children attending out-of-home group child care versus those cared for at home.[60,165-167,234]

Multiple factors contribute to the transmission of infectious agents in the group child care setting (Table 247-1), the most important of which are host factors relating to the immunologic susceptibility of young children. Young infants are experiencing decreased immunity from maternal antibody and thus have increased immune susceptibility. Once infection is established in a child, it can be transmitted easily because of the natural tendency for intimacy in an age group that has not established acceptable toileting practices and is ignorant of basic hygienic practices. Respiratory and gastrointestinal pathogens frequently contaminate toys. Caregivers may have received insufficient training in infection control practices. A lack of policy regarding immunization and health care screening of employees may contribute to the spread of infection. In addition, overcrowding, understaffing, and poorly designed physical environments foster transmission of infectious agents in child care facilities. A lack of or inadequate numbers of hand washing facilities or the availability of sanitizing solutions for both children and providers creates an almost insurmountable barrier to infection control. Major risk factors for spread of infection are related to the age of the participants, the number of children, and the ratio of staff to children. The last is determined in part by the age of the children; younger children require higher staff-to-child ratios. However, in overcrowded situations with inadequate staff, infection can be spread easily because of inappropriate hand hygiene or inattention to other facets of infection control.

Unique factors identified as particularly important in the spread of gastrointestinal organisms are large numbers of diaper-aged children in centers where staff members who diaper children are also responsible for food preparation.[22,105] Separating diaper-aged children from those who are older is important to limit spread of enteric illness. If meals are prepared in the daycare setting, separating this activity from toilet areas is essential. If food is brought from home, it should be transported properly and stored to avoid spoilage. Lack of attention to this issue may result in additional illness. Infants and toddlers are indiscriminate in mouthing objects and fingers, thus contributing to the potential organisms that naturally populate the saliva and the respiratory tract to be transmitted readily from child to child.

Child care centers that operate for profit also are at higher risk for having infectious disease outbreaks, probably as a result of lower staff-to-children ratios.[219] Finally, parents may choose not to withdraw ill children from

TABLE 247-1 Risk Factors for Infectious Disease in Child Care Facilities

Children

Immunologic susceptibility to infectious agents
Lack of toilet training
Natural tendency to intimacy
Frequent oral contact with environment
Lack of awareness and practice of good hygiene

Caregivers

Insufficient training in infection control
Lack of policy regarding immunization
Inadequate screening for infectious diseases

Environmental and Economic Problems

Inappropriate staff-to-child ratios
Overcrowding
Failure to separate age groups
Poorly designed physical layout
  Inadequate or poorly placed sinks
  Failure to separate toilet areas from areas of food preparation
Parental pressure to admit sick children to daycare

attendance at child care voluntarily because of the expense and inconvenience of creating alternative child care arrangements.

MODES OF TRANSMISSION OF INFECTIOUS DISEASES IN OUT-OF-HOME CHILD CARE

The major modes of transmission include respiratory, gastrointestinal (primarily fecal-oral), person-to-person skin contact, and contact with infected body fluids—blood, urine, saliva, or other fluids. Some infections may use more than one mode of transmission (e.g., herpes simplex virus [HSV] can be spread through direct skin contact [if the skin is not intact] or exposure to infected body fluids). The most important pathogens and their modes of transmission of infection in child care are shown in Table 247-2. Respiratory and gastrointestinal infections are the most common causes of illness in infants, toddlers, and preschoolers, regardless of whether these children attend out-of-home child care.[125]

TABLE 247-2 Pathogens and Modes of Transmission of Infection in Child Care

Mode of Transmission	Bacteria	Viruses	Parasites
Respiratory	*Haemophilus influenzae* type b	Adenovirus	
	Streptococcus pneumoniae	Coronavirus	
	Neisseria meningitidis	Human metapneumovirus	
	Streptococcus pyogenes	Influenza A and B	
	Bordetella pertussis	Measles	
	Mycobacterium tuberculosis	Mumps	
	Kingella kingae	Parainfluenza	
		Parvovirus B19	
		Respiratory syncytial	
		Rhinovirus	
		Rubella	
		Varicella	
Fecal-oral	*Campylobacter* organisms	Enteroviruses	*Cryptosporidium parvum*
	Clostridium difficile	Hepatitis A	*Enterobius vermicularis*
	Escherichia coli O157:H7	Adenovirus	*Giardia lamblia*
	Salmonella organisms	Astrovirus	
	Shigella organisms	Calicivirus	
		Enterovirus	
		Rotavirus	
		Astrovirus	
Person-to-person by skin contact	*Streptococcus pyogenes*	Herpes simplex	*Pediculus capitis*
	Staphylococcus aureus		*Sarcoptes scabiei*
			Trichophyton species
			Microsporum species
Contact with blood, urine, or saliva		Cytomegalovirus	
		Hepatitis B	
		Herpes simplex	
		Human immunodeficiency virus

Respiratory

For some microbiologic species causing infection, the mode of transmission is the airborne route. The organism is aerosolized and remains in the air, like cigarette smoke. The microorganisms are present in small droplet nuclei (<5 μm) and are capable of traveling distances on air currents. Direct contact with the infected individual is not necessary for spread of the infection. Agents known to be transmitted by this means include the measles and varicella viruses and *Mycobacterium tuberculosis*.

Most commonly, respiratory organisms are spread by the production of droplets laden with infective particles. When an infected person talks, sneezes, or coughs, droplets containing these microorganisms are formed and expelled, and they may land on the mucosa of another individual. These droplets may also be transmitted directly from mucosa to mucosa when close physical contact occurs. More often, droplets land on nonporous surfaces (e.g., cribs, tables, toys, chairs) or on clothes and paper (fomites) and remain infective for minutes to hours. Hand contact with contaminated surfaces and fomites can result in infection if the hands touch the nasal or conjunctival mucosa.[107,125] Agents that can be transmitted by droplet spread (mucosa to mucosa), from finger to mucosa, or by fomites include most respiratory viruses (respiratory syncytial virus [RSV], rhinovirus, human metapneumovirus, coronavirus, human herpes virus 6 [HHV-6], influenza virus, parainfluenza virus, adenovirus, parvovirus B19, measles virus, mumps virus, rubella virus, and varicella-zoster virus), *Bordetella pertussis*, *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Streptococcus pyogenes*.* Finger-to-mucosa spread of respiratory pathogens is the most important and common mechanism for transmission of viral and bacterial infections.[115] Consequently, hand hygiene that includes hand washing and the use of alcohol-based sanitizers is an essential element of preventing spread of infection.[193,125]

Gastrointestinal

Spread of gastrointestinal organisms is by fecal-oral transmission. The number of organisms required to produce infection will determine whether infection occurs by person-to-person spread or whether a food or fluid intermediary is required. For example, rotavirus, *Giardia lamblia*, and *Shigella* spp. are transmitted readily in small numbers of organisms on the hands (without obvious gross contamination) after person-to-person contact or by touching infected surfaces. In contrast, *Salmonella*, rarely a cause of diarrheal outbreaks in the child care setting, requires large numbers of organisms to produce infection. Accordingly, an intermediary step of food or beverage contamination is required to allow organisms to replicate up to the necessary inocula.

Numerous studies have demonstrated fecal organisms on child care center environmental surfaces with which infants and toddlers have had contact as well as on the hands of care providers.[80,136,230,236] Contamination of the environment is highest when the children are younger than 3 years. This age predilection correlates with the number of children still wearing diapers.[231] Important pathogens, including fecal bacteria, rotavirus, hepatitis A virus (HAV), and *G. lamblia* cysts, are able to survive on environmental surfaces for periods ranging from hours to weeks.[56,144]

Skin

Bacterial, viral, and parasitic infections of the skin can be transmitted by person-to-person spread by direct contact. Bacterial pathogens such as *S. pyogenes* and *Staphylococcus aureus* usually are not primarily invasive unless a break in the integument occurs, such as after minor trauma (e.g., insect bites). HSV may be transmitted from skin or mucosa to skin by direct contact, again only if the skin is broken. Infestations such as scabies and lice are transmitted by person-to-person spread by mobile parasites. The superficial dermatophytes responsible for tinea infections (*Trichophyton*, *Microsporum*, and *Epidermophyton*) are transmitted by person-to-person spread or by contact with infected fomites such as combs, hairbrushes, and hats.

Blood, Urine, and Saliva

Hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and cytomegalovirus (CMV) can be transmitted by blood and sexual activity (presumably resulting in microtrauma, thereby leading to blood exposure). However, transmission of HCV by sexual activity is an uncommon occurrence. Although both HBV and HIV can be demonstrated in urine and saliva, exchange of these body fluids is unlikely to transmit infection. At child care centers, transmission of CMV or HSV probably occurs between attendees by contamination of toys with saliva. Mothers and care providers can become infected with CMV by the finger-to-mucosa route after contamination of hands by urine or saliva.

PATTERNS OF INFECTION IN OUT-OF-HOME CHILD CARE

There are four general patterns of disease manifestations associated with children and adults in the child care setting that are important to recognize (Table 247-3).[101] Most of the increased infectious disease burden found in child care centers is experienced by the children themselves. Certain specific infections, such as those caused by RSV, cause significant illness almost exclusively in the children. However, for several illnesses, adult personnel may experience some of the same respiratory and gastrointestinal symptoms as the children do. Examples of infections for which child care attendees and staff share an increased burden of disease include shigellosis, giardiasis, and invasive meningococcal disease. There are also infections that cause mild or no symptoms in children but have significant repercussions for infected adults, whether parents or child care providers. The most notable of these

*References 82, 90, 91, 104, 107, 108.

TABLE 247-3 **Patterns of Occurrence of Infections Experienced in Daycare**

Patterns of Occurrence	Examples
Clinical manifestation of infection primarily in children	Respiratory syncytial virus and rotavirus infections
Infection affecting children, daycare staff, and close family members	Shigellosis, giardiasis, *Neisseria meningitidis* infection
Inapparent infection in children with clinically important infection in adult contacts	Hepatitis A
Inapparent or mild infection in children and adults but with possibly serious consequences for fetus in pregnant contact	Cytomegalovirus infection, rubella, parvovirus B19 infection, coxsackievirus A16 infection

Modified from Goodman RA, Osterholm MT, Granoff DM, et al. Infectious diseases and child day care. *Pediatrics* 1984;**74**:134-9. Copyright 1984, American Academy of Pediatrics.

diseases is hepatitis A, in which adults have an illness of moderate severity that often leads to extended absences from work. The incidence of hepatitis A disease has declined in the United States since introduction of routine hepatitis A vaccination in children.[41] Finally, with some infections, clinical manifestations in adults are mild, but the infection may have potential effects on the fetus if the child care provider or mother of a child care attendee is pregnant. CMV and rubella virus are associated with severe birth defects if infection occurs in the first trimester. Infection with parvovirus B19 during pregnancy poses a risk for the development of nonimmune hydrops in the fetus.

INFECTIOUS AGENTS IN CHILD CARE

Infections Spread by the Respiratory Route

Upper Respiratory Tract Infections

Respiratory viruses (rhinovirus, coronavirus, RSV, human metapneumovirus, parainfluenza virus, influenza virus, adenoviruses, HHV-6, and Epstein-Barr virus) are the most common causes of infection in preschool-age children.[24,82,91,238] The range of clinical manifestations includes asymptomatic infection, simple upper respiratory tract infection (rhinitis), acute otitis media, pharyngitis, croup, tracheitis, bronchiolitis, and pneumonitis. Disease may be mild or severe and involve a single level or more than one level of the respiratory tree. Children may experience multiple infections with each agent because of antigenic diversity within virus subtypes (e.g., influenza A virus), existence of multiple subtypes (e.g., rhinoviruses, coronaviruses), and failure of immunity to develop after a single exposure (e.g., RSV). Viruses are shed from the site of infection (conjunctiva, nose, throat) even before clinical symptoms develop, thereby rendering control of the spread of these infections in child care difficult. Documentation that children in out-of-home child care (family or large child care centers) experience more respiratory tract infections than those noted in children in home care is ample.* The risk of acquiring infection for children in group or family care is intermediate, between that for large child care centers and home care.[234]

The most common bacterial complication of viral upper respiratory tract infection is acute otitis media. The peak age incidence of otitis media is between 6 and 18 months, similar to that of viral upper respiratory tract infections. Most children have had at least one episode of acute otitis media by the time they reach their second birthday, and approximately one third will have had at least three episodes by that time.[223] Not surprisingly, because the frequency of episodes of viral respiratory tract infections is increased in children attending out-of-home child care, these children experience a notable increase in the frequency of episodes of otitis media.[186,212,215,217,234] Two reviews strongly supported the notion that attendance at child care is a major risk factor for acquiring acute otitis media (Table 247-4)[191,228] Wald and colleagues[234] provided data indicating that the risk of hospitalization for performance of myringotomy with tube placement is highest for children in large child care environments. Similarly, the risk of contracting recurrent acute otitis media and persistent middle ear effusion also is higher for children in child care than for those who receive care at home.[67,86,213,225] Researchers do not recommend that children with mild respiratory infections be excluded from child care or be separated from the group of well children because this strategy has not been shown to achieve an overall reduction in infections for children in child care facilities.

Systemic Viral Infections

Cytomegalovirus. CMV is a common cause of infection in preschool-age children. Most often, the infection is completely asymptomatic.[94] Rarely, the child may experience a febrile illness with lymphadenopathy and hepatosplenomegaly. In the United States, approximately 0.7 percent of newborns are infected with CMV in utero and shed virus at birth.[135] Of these, approximately 90 percent are asymptomatic.[32,214] Sources of CMV in the child care setting are infants and children who have been infected by their mothers by vertical transmission in utero, perinatally (2% to 3%), or post partum through breastfeeding (~6%). Potential sources of transmission in group child care are saliva and urine. Strangert and coworkers[216] reported the isolation of CMV from 7 of 10 children between 21 and 30 months of age in one child care center. Strom[218] found that 13 of 18 (72%) children between 24 and 36 months of age in a single nursery excreted CMV. Children younger than 3 years who acquire CMV after birth excrete CMV in urine and saliva for 6 to 42 months (mean, 18 months).[6] Other investigators demonstrated that peak rates of infection occur in children between 1 and 3 years of age, when viral excretion may be

*References 75, 89, 123, 150, 151, 165, 166, 212, 215, 234.

TABLE 247-4 **Comparisons of Annualized Rates of Acute Respiratory Tract Infections, Otitis Media, and Antibiotic Treatment among Children in Various Modes of Childcare**

Study	Length of Time Observed	Annual Rate of Respiratory Infection (per child-year)	Annual Rate of Otitis Media (per child-year)	Annual Rate of Antibiotic Treatment (per child-year)

documented in as many as 70 percent of children in child care.*

Household contact is a common source of CMV in young children. A population-based study evaluating risk factors for CMV among 4- to 10-year-olds in the United States participating in the Third National Health and Nutrition Examination Survey identified CMV status of household members (mother and siblings) to be a strong predictor of CMV seroprevalence in the child. In this study, previous child care attendance was not shown to be a significant predictor.[214]

Infection in preschool-age children leads to viral shedding documented by positive CMV cultures obtained from swabs of the throat (thereby contaminating saliva) and urine. Transmission probably occurs through fomites (toys and blankets) contaminated with saliva rather than by respiratory droplets.[211] Shedding of CMV is as chronic among infected toddlers in child care centers as it is in children with perinatal or congenital infection.[6,175,176]

The greatest risk for CMV acquisition is during early pregnancy in child care providers or mothers of children attending daycare.[2-5] Such acquisition may lead to clinically evident congenital CMV infection (microcephaly, hepatosplenomegaly, chorioretinitis, psychomotor retardation, and deafness) in approximately 5 to 10 percent of infected children. Another 10 to 15 percent of infants experience occult but potentially damaging infection that results in milder degrees of hearing loss and learning disabilities.[211] Because of the high rates of asymptomatic excretion by children, it is important for child care personnel to be aware of the risks of transmission and to routinely practice appropriate hand hygiene.[15]

Parvovirus B19. Parvovirus B19, the etiologic agent of erythema infectiosum or fifth disease, is spread by the respiratory route. Viral replication, viremia, and nasopharyngeal shedding occur approximately 1 week before the development of clinical symptoms. This benign disease of childhood (in a normal host) may occur in preschool- and school-age children. The classic clinical illness is characterized by an erythematous rash on the face that gives a "slapped-cheek" appearance. This rash may follow a mild, nonspecific illness with fever, myalgias, and headache. The rash progresses after the first day and spreads as a maculopapular eruption beginning on the proximal ends of the extremities and extending to the distal portions and trunk. After several days, these lesions develop into a lacy reticular pattern on the proximal parts of the extremities and then fade.

Less typical presentations include the papulopurpuric gloves-and-socks syndrome, rubelliform rash, and petechial rash. A community outbreak of parvovirus with petechial rash among children in Wisconsin was recently described.[79] Unrecognized in immunocompetent hosts is an infection of the erythrocyte precursor that leads to transient red blood cell aplasia.

In adults, parvovirus B19 infection frequently causes arthralgia and arthritis. Its clinical importance in the context of daycare infections is transmission from an infected preschool-age child to a pregnant mother or

*References 2, 126, 134, 164, 174, 175.

child care provider.[97] Infection of the fetus may lead to nonimmune hydrops secondary to infection of erythrocyte progenitor cells. Estimates of fetal loss when a pregnant woman of unknown antibody status is exposed to parvovirus are 2.5 percent after household exposure and 1.5 percent after occupational exposure in a school or child care facility.[20]

Children are not excluded from group child care once rash is present as they are no longer contagious.[13] Routine exclusion of pregnant women from a child care center where erythema infectiosum is identified is not recommended.[15,110]

Hand, Foot, and Mouth Disease. Hand, foot, and mouth disease (HFMD) is a clinical syndrome characterized by a vesicular exanthem on the distal parts of the extremities and mild stomatitis. Infections are often asymptomatic or mild, but they can be associated with fever and significant pain with the vesicles. Severe stomatitis can lead to dehydration. HFMD is most commonly caused by the enteroviruses coxsackievirus A16 and enterovirus 71, although other enteroviruses have been identified. Enterovirus infections are common among preschool children as shown in seroepidemiologic studies. The disease is mild in children but has a high attack rate.

Transmission is person to person through contact with infected saliva, vesicles, respiratory secretions, or stool. Outbreaks usually occur during summer or autumn months in the United States. Two outbreaks of coxsackievirus A16 HFMD have been reported in children attending child care.[84,85] In recent years, outbreaks of HFMD associated with coxsackievirus A6 have been described worldwide; one outbreak in four geographically distinct states in the United States related to coxsackievirus A6 occurred during winter months. Of the 63 cases, 34 occurred in children younger than 2 years. The symptoms were more severe than those usually associated with coxsackievirus A16.[34]

The most significant clinical concern is the possibility of the development of infection during pregnancy, which may lead to spontaneous abortion.[84,172] Exclusion from group child care is not routinely recommended as symptomatic and asymptomatic children may shed virus in stool for several weeks.[15]

Local Bacterial Infections

***Streptococcus pyogenes* or Group A Streptococci.** Group A streptococci (GAS) are a frequent cause of respiratory and skin infections. The most common expression of infection with GAS is the development of pharyngitis and fever in an elementary school–age child. Usually, the throat infection is accompanied by tender anterior cervical nodes. In classic infection, none of the usual signs of viral upper respiratory disease—coryza, cough, and conjunctivitis—are present. Illness peaks in the late winter and spring. In contrast, streptococcal infection of a preschool-age child or child in group care takes the form of a protracted upper respiratory infection. Specifically, these patients have low-grade fever, persistent nasal discharge, anorexia, and cervical adenopathy.

Although exposure of child care attendees to an index case of streptococcal pharyngitis can be assumed to result in secondary cases, relatively few epidemics of GAS infection have been reported in child care facilities.[83,122,207] An outbreak occurred in a child care center in which preschool children shared facilities with kindergarten children in an after-school program. During a 3-month period, 47 percent of the child care population had positive pharyngeal cultures for GAS or positive results on a rapid antigen detection test.[207]

GAS can also be transmitted person to person by skin-to-skin contact and colonize healthy skin. Superficial infection (impetigo) may then occur at sites of traumatized skin (e.g., insect bites or scratches). Often, GAS and *S. aureus* are both isolated from sites of impetigo. Erysipelas and cellulitis due to GAS can result in an abrupt onset of fever and dramatic cutaneous erythema and tenderness often accompanied by regional adenopathy. Outbreaks of perianal cellulitis have been reported from child care centers.[163,195] A cluster of 12 cases of perianal cellulitis, characterized by a well-demarcated rash around the anus with itching, rectal pain, blood-streaked stools, and occasionally a purulent discharge, was reported from a kindergarten setting in Denmark.[178]

The diagnosis of streptococcal skin infection can be made by careful performance of wound or surface cultures (obtained after careful cleansing of the periwound area) or examination of tissue aspirates. Spread of typical impetigo occurs commonly within families and presumably also would occur within child care centers. Children with GAS infections of the throat or skin should be excluded from group child care for 24 hours after the initiation of appropriate antibiotic treatment.

Invasive Bacterial Diseases

***Kingella kingae*.** *K. kingae* is a fastidious gram-negative coccobacillus that colonizes the oropharynx and is becoming increasingly recognized as an important cause of osteoarticular infections in young children (younger than 3 years); it has also been identified in cases of bacteremia and endocarditis.[78,241] Colonization rates are highest in children younger than 2 years. Preceding stomatitis and upper respiratory viral infections have been recognized as risk factors for invasive disease.[18,78] Outbreaks of osteomyelitis and septic arthritis associated with *K. kingae* have been reported in child care settings in Minnesota[138] and Israel.[242] In 2007, a cluster of cases in a daycare center in North Carolina was reported in association with a case of endocarditis. Genetically similar *Kingella* isolates were obtained from asymptomatic children in the same daycare.[200] Colonization rates in these child care centers ranged from 7 to 42 percent.

***Neisseria meningitidis*.** *N. meningitidis* is a gram-negative, polysaccharide-encapsulated diplococcus found colonizing the nasopharynx. With the reduction of invasive *H. influenzae* type b and *S. pneumoniae* disease due to effective immunization strategies, *N. meningitidis* is the leading cause of bacterial meningitis in the United States. Meningococcemia is a major manifestation with significant morbidity. Less commonly, pericarditis, pneumonia,

arthritis, otitis media, or epiglottitis can occur. Active surveillance (1998-2007) in the United States observed the highest rates of invasive meningococcal disease among infants younger than 1 year, although the case-fatality rate was the lowest in this age group.[57]

The pathogenesis is hematogenous dissemination from the nasopharynx as a site of colonization. Transmission is person to person through infected respiratory droplets. Household contacts exposed to patients with meningococcal disease have a significantly higher risk of acquiring infection than does the general population.[160,162]

Secondary spread of infection with *N. meningitidis* has been recognized as a potential risk, especially in situations of crowding, such as in military barracks and college dormitories. In addition, reports suggest that the risk of acquiring secondary disease caused by *N. meningitidis* is increased in the child care setting.[131,147,169,192] In a Belgian report,[71] exposure in a daycare nursery during a prolonged meningococcal epidemic conferred a risk for infection that was 76 times greater than that in children of similar age who received care at home.

Prompt institution of chemoprophylaxis is the recommended strategy for management of all intimate contacts of a person with invasive *N. meningitidis* disease. Rifampin for 2 days (5 mg/kg/dose in infants <1 mo or 10 mg/kg every 12 hours to a maximum 600 mg) is the preferred regimen for children. Alternative medications in children and adults include single doses of ceftriaxone, azithromycin, or ciprofloxacin. Throat culture to identify those who require prophylaxis is not recommended. In an outbreak, meningococcal conjugate vaccine may also be used for prevention of secondary cases if the outbreak serotype is one that is contained in the vaccine.[15] Children with meningococcal disease should be excluded from child care until they have received antimicrobial treatment for 24 hours.

Two quadrivalent conjugate vaccines are licensed in the United States. Both contain components against the serogroups A, C, Y, and W135 and are recommended for routine administration to children at the age of 11 years or as young as 9 months for those at high risk for meningococcal disease (e.g., children with functional or anatomic asplenia, complement deficiencies, or travel to areas of the world where meningococcal disease is hyperendemic or endemic[15]). Serogroup B is present in the United States and accounts for 50 to 60 percent of disease in infants,[57] but it is not yet included in the vaccine.

***Mycobacterium tuberculosis*.** Infection caused by *M. tuberculosis* is one in which the direction of transmission is from an adult or adolescent to a child. Young children rarely are contagious; therefore, the identification of tuberculosis in a young child is a sentinel event and should prompt public health investigation to identify the index case. Cases of tuberculosis in children have been traced to attendance at daycare.[98,148,168] Screening of personnel who work in child care settings, both staff and volunteers at high risk for tuberculosis exposure, is essential to prevent childhood tuberculosis disease. Children identified with active tuberculosis are excluded from group child care until effective therapy is initiated with good adherence and they are determined to be noninfectious to others.[13]

Infections of the Gastrointestinal Tract

Parasitic Infections

***Giardia lamblia*.** *G. lamblia* is the most common intestinal parasite of humans and a major cause of diarrhea in child care centers.[27,185,199] Infection can be caused by the ingestion of as few as 10 cysts. Transmission is fecal-oral and most commonly results from person-to-person spread, although waterborne outbreaks have been documented.[137] Parents of daycare attendees are at risk for acquiring infection.[179] Asymptomatic excretion does occur and is most common in children younger than 3 years. Demonstration of *G. lamblia* cysts on environmental surfaces indicates additional potential for transmission.[56] Infection with this parasite causes infestation of the duodenum and proximal jejunum and results in asymptomatic carriage more often than clinical disease.[128] After an incubation period of approximately 2 weeks, symptomatic patients experience diarrhea, intermittent abdominal pain, anorexia, and flatulence. The most notable feature of the infection is its tendency to become protracted, thereby leading to weight loss, failure to thrive, and anemia. The diagnosis is made by identifying organisms by sensitive immunoassays or direct fluorescent antibody assays in stool samples or occasionally by examination of duodenal aspirates or intestinal biopsy specimens. After resolution of symptoms, either by virtue of treatment or by spontaneous cure, cysts may be shed for a long time.[128] Treatment is not recommended for asymptomatic individuals shedding *G. lamblia* cysts. For symptomatic individuals, treatment may be undertaken with metronidazole, tinidazole, or nitazoxanide. Relapses occur in approximately 15 percent of patients, often requiring a second course of treatment.

***Cryptosporidium*.** *Cryptosporidium* parasites can cause diarrhea in immunocompromised hosts, but infection usually results in self-limited illness in immunocompetent children and adults.[59] The usual clinical symptoms are watery diarrhea and low-grade fever with abdominal pain and weight loss. Vomiting occurs in approximately 30 percent of patients.

Cryptosporidium oocysts can be found in the soil, in water, in food, or on surfaces contaminated by feces. Transmission is fecal-oral. The most common source of transmission and outbreaks has been the swallowing of contaminated water (either drinking or recreational).[153] Increased incidence of cryptosporidiosis occurs during summer and early fall months, which corresponds to months with increased recreational water activities.[45] Like *G. lamblia*, *Cryptosporidium* has a low infectious dose for humans. Infection can occur with as few as 10 to 30 oocysts.[52] Spread of infection is facilitated in daycare centers because oocysts shed in the feces of infected persons are highly resistant to common disinfectants, including chlorine. Many outbreaks of diarrhea caused by *Cryptosporidium* have been reported from daycare centers.* Asymptomatic children and adults shed oocysts for weeks after infection.

*References 10, 11, 58, 62, 113, 222.

The diagnosis is made by examination of stool for oocysts with special stains such as the Kinyoun acid-fast stain. Alternative methods include direct fluorescent antigen detection and enzyme immunoassays specific for *Cryptosporidium* antigen. Routine stool examinations for ova and parasites can miss the cryptosporidium oocysts. Recommended treatment is a 3-day course of nitazoxanide. Treatment can reduce the duration of diarrhea and shedding of oocysts in stool.[12] Exclusion from child care is recommended until the child is asymptomatic.

Bacterial Pathogens

Shigella. Infection with *Shigella* organisms causes illness of variable severity but easy transmissibility. Accordingly, *Shigella* is one of the most common causes of diarrhea outbreaks in the daycare population,[35,21,96] and *Shigella* infection was among the first enteric diseases recognized to be spread in daycare centers. Infection can be caused by as few as 10 to 100 organisms. Although a low inoculum is sufficient to cause infection, the organism does not survive well outside the human host. Fecal-oral transmission by person-to-person contact is the primary mode of transmission. However, contaminated environmental objects or food can be the agents of transmission. Infection with *Shigella* may be caused by one of four species (*S. sonnei*, *S. flexneri*, *S. dysenteriae*, and *S. boydii*).

Shigellosis is primarily a disease of young children.[15] In outbreaks, younger children have the highest attack rate and are the most effective transmitters of infection.[224] Daycare personnel and family contacts also experience high attack rates.[121,221] After an incubation period of several days, fever and watery diarrhea, followed by crampy abdominal pain, tenesmus, and mucoid bloody stools, occur in patients with classic disease. In many cases, the illness is mild and self-limited and is indistinguishable from other causes of gastroenteritis. The presence of fecal leukocytes on examination of stool provides supportive information; stool culture is diagnostic.

Treatment of shigellosis with an appropriate antimicrobial effectively terminates the illness. Antimicrobial treatment decreases the duration of symptoms and fecal shedding. Untreated persons continue to excrete organisms for several weeks. Susceptibility varies both within and outside the United States, and therefore testing of stool isolates is indicated. Isolates with increased resistance to ampicillin and trimethoprim-sulfamethoxazole are being reported.[21,132]

Children should be excluded from child care if there is frequent stooling and difficulty containing stool in a diaper, frequent accidents in toilet-trained children, or blood or mucus in stool. They can return to child care once treatment is completed and two stool cultures collected at least a day apart are negative.

Campylobacter jejuni. *C. jejuni* is a common cause of bacterial diarrhea in children in the United States, but it is less likely than *Shigella* to cause outbreaks of diarrheal disease in daycare centers.[129,145,173] Most often, a high inoculum of *Campylobacter* is required to produce infection, thereby necessitating a food or water vehicle, such as contaminated foods, undercooked poultry, or unpasteurized milk.[81] Less often, transmission can occur by person-to-person spread of smaller numbers of organisms. The clinical findings are variable, but the usual onset includes fever, abdominal pain, and diarrhea. Watery diarrhea and low-grade fever with only modest constitutional signs of illness also may be observed. Abdominal pain may be present and, if severe, may mimic appendicitis or intussusception. The illness usually lasts between 3 and 7 days. The diagnosis can be made by culture of stool; examination of stool by darkfield microscopy or direct smear may be informative if it is performed by an experienced observer.

Treatment with erythromycin and azithromycin is effective in terminating excretion of the infective organism, which may be important in controlling epidemics or outbreaks. The impact of macrolides on the clinical course of disease is variable. Without treatment, an individual may shed bacteria up to 3 weeks. Antibiotic susceptibility patterns of the organism should be used to guide treatment.

Salmonella. *Salmonella* is the most common cause of bacterial diarrhea in many parts of the United States, but it is an uncommon cause of gastroenteritis outbreaks in daycare centers.[149] Because the organism is widespread in nature and has 2200 different serotypes, it has been difficult to control. Infection usually occurs after the ingestion of contaminated food or beverages. The most common serotypes in the United States are *Salmonella* serotype *typhimurium* and *Salmonella* serotype *enteritidis*.

Numerous outbreaks have been associated with ingestion of contaminated food or contact with colonized reptiles such as turtles.[111] Person-to-person spread seldom occurs, except in infancy, when the infective dose is low.[239] Children younger than 4 years have the highest incidence of symptomatic *Salmonella* infection.

The most common expression of infection with *Salmonella* is uncomplicated gastroenteritis. The illness begins approximately 12 to 36 hours after exposure and often is characterized by initial vomiting followed by diarrhea. Abdominal pain and fever are frequent accompaniments; occasionally, stools contain mucus and blood. Although most cases are self-limited, *Salmonella* infection can be distinguished from other causes of gastroenteritis by its occasionally protracted course.

Children younger than 5 years may excrete *Salmonella* organisms up to 3 months after infection. This highlights the great need for attention to hygiene in a daycare setting, particularly the separation of the activities of food handling and diaper changing. Exposure to reptiles and rodents should be limited.[15]

The diagnosis is made by culture of stool. In general, antimicrobials are not recommended unless bacteremia is documented or the episode becomes protracted and severe. Antimicrobial therapy can prolong the duration of fecal shedding of organisms. Management of special hosts, such as neonates and immunocompromised patients, is controversial. Although some authors recommend antimicrobial therapy for these groups, few data support this recommendation. For nontyphoidal *Salmonella* infection, exclusion from daycare is recommended

until the diarrhea resolves and the child is able to participate fully in care. Negative stool cultures are not required. Obtaining stool cultures from daycare contacts or the index case in convalescence is not necessary.[224] A high rate of asymptomatic colonization with *Salmonella* of multiple serotypes has been documented in daycare centers in Mexico.[171]

If *S. typhi* is isolated, temporary exclusion is recommended. Return to care is dependent on three negative stool cultures and clearance by a health professional for children younger than 5 years.[13]

Clostridium difficile. *C. difficile* is the classic cause of pseudomembranous colitis in patients who have received or are receiving antimicrobial agents, and it rarely causes disease unassociated with antimicrobial use. The organism, a gram-positive, spore-forming rod, is distributed widely in soil and in the gastrointestinal tract of humans. It frequently is found colonizing the gastrointestinal tract in up to 50 percent of asymptomatic infants. Infection is acquired by ingestion of spores from the environment or an infected person. Disease is a consequence of the elaboration of toxin or toxins by vegetative organisms. Hospital environments and daycare facilities are reservoirs for the organism.[139,140] During outbreaks of *C. difficile* diarrhea in daycare centers, environmental contamination is increased, as is recovery of *C. difficile* from the hands of children and staff.[140]

Clinical symptoms include fever, diarrhea, and abdominal cramps. Stools may contain blood and mucus. The illness varies in severity from mild to life-threatening. The diagnosis of *C. difficile* gastroenteritis is made by recovery of the toxin from a stool sample analyzed by enzyme-linked immunosorbent assay or nucleic acid techniques. Treatment includes cessation of antibiotics and supportive care. Specific antimicrobial therapy may be necessary to achieve clinical cure. Metronidazole is recommended for initial treatment in mild or moderate disease. Oral vancomycin is used initially in severe disease. There are newer agents being studied for the treatment of *C. difficile* in children. Children and personnel should be excluded from group child care until they are asymptomatic.

Escherichia coli. Infection with Shiga toxin–producing strains of *E. coli* (STEC, the most common of which is *E. coli* O157:H7) is characterized by bouts of often bloody diarrhea and abdominal pain. Significant morbidity may occur, with approximately 5 to 10 percent of infected children developing hemolytic-uremic syndrome.

Ruminants such as cattle are the main reservoir for STEC. Transmission occurs by the fecal-oral route through contaminated food or water, fomites, or direct contact with an infected person or carrier animal. Numerous outbreaks have occurred in association with raw meat, unpasteurized milk, contaminated foods, and recreational water.

Outbreaks have been reported in child care settings. In 1986, an outbreak of diarrhea caused by *E. coli* O157:H7 was reported from a daycare attended by 107 children.[210] Thirty-four percent of attendees became ill, with a significant increase in risk for younger children. Approximately one third of the children with diarrhea had bloody stools, and hemolytic-uremic syndrome developed in three children. Although infection with *E. coli* O157:H7 usually occurs after the ingestion of contaminated foods, person-to-person spread of infection most likely occurred in this epidemic. The diarrheal illness also was documented in family members of ill children.

Subsequent epidemiologic studies in Minnesota confirmed the mode of transmission for *E. coli* O157:H7 to be person to person in the daycare setting.[26] Accordingly, symptomatic children should be excluded from daycare until stools are formed and two stool specimens obtained 24 hours apart are culture negative for *E. coli* O157:H7 (obtained 48 hours after any antibiotic treatment).[15] Unfortunately, fecal shedding of *E. coli* O157:H7 may be prolonged in young children.[220]

A systematic analysis of 90 outbreaks occurring worldwide (1982-2006) identified approximately 20 percent of cases arising from secondary spread. The highest proportion of secondary cases was among children younger than 6 years.[208]

E. coli O157:H7 is recovered from stool samples after being plated on MacConkey-sorbitol agar. Sorbitol-negative colonies of *E. coli* are picked and screened with O157 antisera by tube agglutination. Several sensitive, specific, and rapid immunologic assays for detection of Shiga toxin are available and should be used along with culture for identification.[44] Antibiotic treatment is not recommended for persons with diarrhea caused by *E. coli* O157:H7.[240]

Viral Pathogens

Norovirus. The calciviruses norovirus and saporovirus are nonenveloped RNA viruses that have a worldwide distribution and are a cause of human gastroenteritis. Saporovirus is much less frequently an agent of gastroenteritis than is norovirus. Transmission is by person-to-person spread through the fecal-oral route or through contaminated food or water. Noroviral particles found in vomitus are potentially infectious through the airborne route during forceful vomiting. Norovirus is antigenically diverse; therefore, repeated bouts of diarrhea may occur with exposure to different viral variants. Norovirus is highly contagious; a very small inoculum is required to establish infection. Outbreaks frequently are observed in closed populations, including child care centers and on cruise ships. The attack rate usually is high. Two reports highlighted the transmissibility of this agent in the child care setting.[102,127]

Astroviruses. Astroviruses are common causes of diarrheal outbreaks in daycare[9,206] and other closed populations. Children younger than 4 years are infected most commonly, and the illness has a winter predominance. Transmission usually is by person-to-person spread by the fecal-oral route. This illness is indistinguishable from the other viral causes of gastroenteritis, presenting with watery diarrhea that may be accompanied by vomiting, fever, or abdominal pain. Healthy, asymptomatic individuals can shed virus for several weeks.

Infections Spread by Skin Contact

Methicillin-Resistant Staphylococcus aureus *(MRSA)*

S. aureus is part of the endogenous flora of humans; the nose is the primary site of carriage in adults and children. At any one time, approximately 30 percent of people carry *S. aureus* in their anterior nares.[155] Transmission is primarily through person-to-person skin contact but also through direct contact with contaminated environmental surfaces.

During the 1990s, there was an increasing prevalence of disease caused by methicillin-resistant *S. aureus* (MRSA) in children without predisposing risk factors, such as contact with the health care system.[38,116] Studies of colonization in daycare centers demonstrated likely transmission within the child care setting.[1,117,201]

This community-acquired MRSA (CA-MRSA) has a genetic predisposition for causing skin and soft tissue infections (e.g., abscesses, carbuncles, and furuncles). More rarely, CA-MRSA may cause severe invasive infections, such as bacteremia, endocarditis, osteomyelitis, pyomyositis, or necrotizing pneumonia. Methicillin-susceptible strains of *S. aureus* cause similar clinical findings, although to a lesser extent. Recent surveys of the incidence of CA-MRSA disease in hospital and community settings (including child care) have demonstrated the most rapid increase among young children.[63,92,161]

A survey of MRSA isolates from national databases derived from hospital discharges during a 10-year period from 1998 to 2007 demonstrated a 16-fold increase in hospitalization rates for CA-MRSA infections in children. The proportion of *S. aureus* abscesses caused by the CA-MRSA phenotype increased from 8.7 to 60.3 percent in this same period.[161] An epidemiologic survey (2001-2002) using data from the Active Bacterial Core surveillance program demonstrated that disease incidence related to CA-MRSA was highest among individuals younger than 2 years. Of the 1647 patients with CA-MRSA isolates, 77% had skin and soft tissue infection.[92]

Children with documented MRSA should not be excluded from child care for colonization or for skin or soft tissue infections. Any open and draining wounds should be covered.

Scabies

Scabies is an infection of the skin caused by infestation with the female mite *Sarcoptes scabiei*. It is an obligate parasite that undergoes its complete life cycle in humans. Transmitted by person-to-person spread from an infested individual, the mite buries itself beneath the stratum corneum and burrows along for its 30-day life span while laying two or three eggs per day. The larval and nymphal mites scatter after hatching to embed themselves in skin at distant sites. Some 3 to 6 weeks later, a pruritic eruption (worse at night) develops and leads to excoriation, bleeding, and crusting. The distribution of lesions varies with age. In adults and older children, the eruption, which consists of papules, vesicles, and nodules, occurs commonly in the interdigital spaces of the hands, on the extensor surface of the elbows, and around the umbilicus, waist, axillary lines, and genital area. In infants and young children, vesicular and eczematous lesions can be found on the hands and feet as well as on the face and head.

The diagnosis is made by scraping the lesions and demonstrating the mite, ova, or mite feces. Treatment of the index case should be undertaken with a scabicide, preferably 5 percent permethrin in children older than 2 months, applied to the entire body. It is applied from the neck down in older children and adults. Lindane is no longer recommended. Asymptomatic contacts should be treated simultaneously because they may be infected unknowingly and may be capable of transmitting the mite during this asymptomatic period. Clothing and bed linens that had contact with the skin of infected persons during the 3 days before treatment should be laundered in hot water. Alternatively, items can be stored in plastic for at least 4 days.[13]

Although scabies is spread primarily by intimate personal contact, skin-to-skin transmission can result from prolonged casual contact, as occurs in institutional settings, nursing homes, and daycare centers.[194] Mites can survive on inanimate surfaces for 2 to 3 days, a period that permits transmission by fomites such as clothes, bed linen, and furniture. An outbreak of scabies was reported in a hospital-affiliated daycare facility. Elimination of the problem required a coordinated effort with simultaneous treatment of all potentially infected individuals.[194] An infected child should be excluded from daycare until treatment has occurred, which is usually overnight.

Head Lice

Head lice infestation occurs commonly in children attending daycare, preschool, and elementary school as a consequence of infection with *Pediculus capitis*. It affects children of every socioeconomic status. The insect, a hemophagocytic ectoparasite, obtains nourishment by sucking capillary blood from the scalp. Female lice attach egg cases (nits) to the hair shafts at or very near the scalp. The eggs hatch 8 to 11 days later, and the louse nymphs are released.

The diagnosis is often made when the symptoms of scalp pruritus, excoriation, pyoderma, and regional lymphadenopathy cause the caregiver to inspect the scalp closely. Nits are observed readily, although live lice may be difficult to see, especially in light infestations. Transmission is by direct head-to-head contact and, less commonly, spread by fomites or live lice.

Treatment is with topical pediculicides, used as directed with care. These include permethrin lotions and pyrethrin-based products. Resistance has been identified with these products. In addition, products such as malathion, benzyl alcohol lotion, spinosad suspension, and ivermectin lotion may be used. Lindane shampoo is no longer recommended because of safety concerns.[15] Nits can be removed mechanically with spiral combs. Clothing and infested bedding can be washed on high temperatures (130° F [54.4° C]). Children should be excluded from the group child care setting at the end of the day until treatment has occurred.[13]

Infections Spread by Contact with Blood, Urine, and Saliva

Cytomegalovirus

CMV can be transmitted by blood, urine, and saliva as described earlier.

Herpes Simplex Virus

HSV is a DNA virus that commonly infects mucosal surfaces. Inoculation and replication at the site of infection are followed by the establishment of latency in sensory ganglia. Primary infection with HSV type 1 most often occurs in the oral mucosa. Approximately 15 percent of children 3 years of age and younger will have gingivostomatitis as the manifestation of primary HSV-1 infection.[19,50,196] Symptoms of primary infection range from asymptomatic to severe, painful ulcerations of the oral mucosa and perioral regions, resulting in dehydration because of inability or reluctance to swallow. Stomatitis may be accompanied by signs of upper respiratory infection, fever, pharyngitis, and regional lymphadenopathy. Reactivation of virus is manifested most often by asymptomatic shedding of virus in the saliva or the presence of labial ulcerations (e.g., cold sores). Other sites of recurrent lesions may be seen (e.g., herpetic whitlow resulting from a child's autoinoculating his or her fingers through sucking). Children who have perinatally acquired HSV may have recurrent infections at sites related to the original infection.

Transmission in a group child care setting is through direct contact with herpetic lesions or infected saliva (e.g., through sharing of mouthed objects). Studies have demonstrated high attack rates of HSV infection and stomatitis in orphanages[50,106] and daycare settings.[196,142] One study of 90 children in a daycare center (aged 0 to 37 months) in Japan identified four clusters of infection during the 4 years of observation. Horizontal transmission was confirmed by genetic analysis of the isolated viruses.[142]

Children with herpetic gingivostomatitis do not need to be excluded from group care unless there is difficulty in controlling drooling. Children and staff with recurrent infection do not need to be excluded.[13] Covering of active lesions with clothing or bandages during child care is sufficient.[15]

Human Immunodeficiency Virus

The potential transmission of HIV by blood or body fluid exposure can cause great concern. However, the risk of nonsexual, nonpercutaneous transmission is low. The risk for health care workers with percutaneous exposure to known HIV-infected blood by needle stick has been estimated to be fewer than 3 in 1000 exposures.[25] To date, HIV infection has not been reported to be transmitted in a child care center.

There are rare case reports of transmission of HIV within households with an infected member.[36,88,95,233] In most cases, transmission occurred in a setting with ongoing exposure of nonintact skin (e.g., eczema) or mucosal surfaces to infected blood or body fluids. Recent reports identified three children who were likely infected through the practice of food premastication by an HIV-infected caregiver. In two cases, the premastication occurred at a time the caregiver had bleeding gums or mouth sores.[95] In light of its rare horizontal transmission to nonsexual contacts within households with an infected member, HIV would not be expected to spread in child care.[93,133]

One potential high-risk situation may involve HIV-positive children who are persistent biters or who have extensive weeping skin lesions. However, several reports indicate a lack of transmission to individuals bitten or scratched by a person infected with HIV.[77,190,205,226]

Since the institution of the guidelines to identify HIV-positive women during pregnancy and to intervene with peripartum antiretroviral medication use,[37] the incidence of perinatal HIV infection in the United States has declined dramatically.[40] Recent estimates are that fewer than 200 infants are born in the United States with HIV infection. Children who are born in countries with high rates of HIV infection and immigrate or are adopted into the United States should be screened for HIV infection.

Parents and guardians need not disclose their child's HIV status to child care staff. Personnel should be trained in the use of standard precautions and use gloves for potential exposures to blood or body fluids. Children who have weeping skin lesions that cannot be covered or bleeding problems should be excluded from child care until the condition is resolved.[13]

VACCINE-PREVENTABLE DISEASES

Since the beginning of the vaccine era in the early 20th century, many of the infectious illnesses that were easily spread among children and household contacts have now been significantly decreased in number. A comparison of annual morbidity of 10 infectious diseases for which universal vaccination is recommended for U.S. children showed approximately 95 to 100 percent decrease in morbidity for all infections (2007 vs. baseline 20th century annual morbidity data).[181] There are currently 14 vaccines that are recommended for children in the United States before entrance into elementary school. These provide protection to young infants and children through the development of individual and herd immunity. However, there continues to be a need for awareness of the clinical presentations of vaccine-preventable diseases as unimmunized or underimmunized children (by family choice or due to immunocompromised status) may be exposed in group child care settings. Many infections are still present in high rates in other countries, and children born in these countries who immigrate may be asymptomatic carriers of infectious organisms (e.g., HAV).

Diphtheria

At the time of this writing, there has not been a case of diphtheria in the United States since 2003, although it is

still present and endemic in countries with low rates of vaccination. Diphtheria is caused by production of toxin by the bacterium *Corynebacterium diphtheriae*. Clinical presentation may include nasal symptoms, membranous pharyngitis, obstructive laryngotracheitis, or skin manifestations. The prominent symptoms are usually a severe sore throat and croup accompanied by toxemia.

Corynebacterium diphtheriae is spread by respiratory droplets from people with infection or who are carriers after intimate contact. Individuals are susceptible if they have not been immunized or have been immunized only partially. Treatment is with antitoxin and antibiotics (erythromycin or penicillin). Prophylaxis can be accomplished with erythromycin or penicillin if an individual is found to be a carrier. Immunization with a diphtheria toxoid–containing vaccine is effective in preventing disease and spread of infection.

Haemophilus influenzae Type b Infection

Haemophilus influenzae type b (Hib) used to be the major bacterial pathogen of childhood and was responsible for meningitis, epiglottitis, pneumonia, facial cellulitis, and septic arthritis. These infections occurred in children between 2 months and 5 years of age, with a peak occurring in those between 6 and 18 months of age. The organism colonizes the nasopharynx before becoming bloodborne; hematogenous dissemination results in a distant focus of infection. Infected children usually have a several-day history of mild upper respiratory symptoms followed by an abrupt onset of high fever and localized symptoms indicating the site of infection (e.g., irritability or seizures in central nervous system infection, cutaneous findings in cellulitis). Colonized individuals who lack anticapsular antibody are susceptible to the development of invasive disease.[103]

The availability and universal use (in infancy) of effective vaccines for the prevention of Hib infection have changed the epidemiology of infections caused by this pathogen dramatically.[204] Conjugate vaccines were introduced in 1987. Although there has been a dramatic decline in invasive disease since then, cases of invasive Hib disease are still reported sporadically. The incidence of Hib disease between 1999 and 2008 remained highest among children younger than 1 year.[154] Schulte and coworkers[197] reviewed the pattern of invasive Hib infection in New York State. These investigators demonstrated a dramatic decline in the incidence of Hib disease in children younger than 5 years, both those in daycare and those in home care. The decrease in cases of infection attributable to Hib occurred in children attending daycare centers before it was observed in non-daycare attendees, perhaps because of the requirement for Hib vaccine before enrollment in daycare. Rarely, cases are reported among fully vaccinated children in a daycare center.[159] In 2007, a voluntary recall of Hib vaccine by one supplier led to underimmunization of children younger than 15 months as immunization schedules were adjusted. Minnesota reported an increase in invasive disease (five children 3 years of age or younger) in 2008, higher than the previous 16 years. The majority of children were underimmunized because of parental refusal. A simultaneous survey of nasopharyngeal Hib carriage showed low rates of carriage in this age group.[152]

The virtual disappearance of this once common and serious problem and the high immunization rates with Hib vaccine obviate a lengthy discussion about the need for rifampin prophylaxis after exposure to cases of invasive disease. In the rare instance of invasive Hib disease occurring in a child care center housing unimmunized or partially immunized children (younger than 4 years), all daycare contacts (adults and children) should receive rifampin 20 mg/kg/day once daily for 4 days to a maximum dose of 600 mg.

Streptococcus pneumoniae Disease

Pneumococci are a common cause of bacterial infections of the upper and lower respiratory tracts, including otitis media, sinusitis, and pneumonia.[198] As respiratory pathogens, they also cause other upper respiratory tract infections, such as conjunctivitis, and important systemic illnesses, including occult bacteremia, bacteremic periorbital cellulitis, and meningitis. Multiply antibiotic–resistant *S. pneumoniae*, a problem that began in the 1960s, is now widespread in South Africa, in large parts of Europe, and, since 1990, in the United States.

S. pneumoniae is spread easily in the child care setting related to the high rates of nasopharyngeal carriage in young children. The ease of transmission of penicillin-resistant *S. pneumoniae* (tracked by antibiotic resistance patterns, capsular types, and genetic patterns) in the child care setting has been demonstrated amply.[76,114,183,184] In addition, although the precise risk of the acquisition by children of secondary cases of pneumococcal disease in daycare versus home care is unknown, several outbreaks of invasive *S. pneumoniae* disease in daycare centers have brought greater attention to this issue.[53,61,184]

A pneumococcal conjugate vaccine containing seven common serotypes of *S. pneumoniae* (PCV7) was licensed in the United States in March 2000. The use of PCV7 and other pneumococcal conjugate vaccines has been shown to reduce both nasopharyngeal colonization with the serotypes of *S. pneumoniae* contained in the vaccine (including the carriage of antibiotic-nonsusceptible *S. pneumoniae*)[64,65,109] and rates of invasive disease due to vaccine serotypes.[143] This secondary effect of the conjugate vaccines has resulted in a decrease of both colonization and disease among the contacts of vaccinees.[100]

In a large field trial conducted at the Kaiser Permanente Vaccine Study Center with the heptavalent vaccine, the vaccine performed very well. The trial achieved a 93 percent reduction in invasive disease (meningitis and bacteremia), a 73 percent reduction in consolidative pneumonia, and a 7 percent reduction in episodes of otitis media.[29] The implementation of PCV7 also had an impact on the rates of carriage and disease caused by penicillin-nonsusceptible strains. Active surveillance data from 1996 to 2004 demonstrated an 81 percent decrease in invasive disease caused by penicillin-nonsusceptible pneumococci in children younger than 2 years.[143]

However, soon after the introduction of PCV7, replacement pneumococcal strains were identified in the nasopharynx of healthy, asymptomatic children and were

also the cause of invasive disease (e.g., meningitis or bacteremia).[66,118,177] A 13-valent pneumococcal conjugate vaccine (PVC13) that incorporated antigens of the more invasive pneumococcal serotypes (e.g., serotype 19A) was licensed in 2010 and is now recommended for the universal vaccination of infants.

Influenza

Influenza is a common cause of upper respiratory infection in preschool-age children. The severity of infection is variable, from mild nasal congestion to a severe sepsis syndrome. Influenza can cause significant morbidity in people of all ages; children younger than 5 years carry a large burden of disease. Secondary lower respiratory tract infections with *S. aureus* or *S. pneumoniae* among other pathogens contributes to much of the morbidity in severe cases.

Influenza is transmitted by person-to-person spread through infected droplets with a cough or sneeze or indirectly from contaminated objects. Secondary transmission to household and child care contacts is a common occurrence.

Epidemics occur seasonally during the colder months of the year. However, in 2009-2012, a pandemic of influenza A (H1N1) strain was seen globally that began in the spring. During this pandemic, there was an observed fourfold increase in mortality among children compared with previous years.[49]

Because of variation in influenza A antigens, components of influenza vaccines are adjusted annually. The antigens for H1N1 have subsequently been included in the seasonal vaccine. There is a trivalent inactivated influenza vaccine and a live attenuated viral vaccine for seasonal immunization of persons older than 6 months.[15]

Children with influenza should not be excluded from child care unless they are unable to participate or if caring for the child would compromise the available staff.[13]

Varicella

Varicella, or chickenpox, is a highly contagious infection that is spread easily by the airborne route and by respiratory droplets. It is characterized by a pruritic, generalized vesicular rash that occurs in one to six crops, each crop separated by 24 to 36 hours. Fever usually is mild. The most common complication is secondary bacterial pyoderma, and although it is uncommon, pneumonia and secondary invasive infection by *S. pyogenes* can cause significant morbidity. Varicella-zoster virus remains latent in sensory ganglia after primary infection but can be reactivated as herpes zoster or "shingles," in which case it is manifested as a vesicular eruption involving one to three sensory dermatomes. If infection is acquired in early pregnancy, varicella embryopathy (limb bands or amputation) has been noted in a small fraction of children.

In 1995, live attenuated varicella vaccine became available for universal use in the United States in children between 12 and 18 months of age. The availability of this vaccine altered the epidemiology of varicella in the United States dramatically. The vaccine has been demonstrated to be highly effective during most outbreaks of varicella in child care[55,130] and in clinical practice.[232] The general effectiveness of the vaccine is 83 to 86 percent against all forms of the disease and 97 to 100 percent against moderate to severe disease. However, through active surveillance, cases of breakthrough disease in children who had received one dose of varicella vaccine were reported. Outbreaks were reported in elementary schools with high rates of vaccine coverage.[39,227] Breakthrough disease was seen in a daycare in Connecticut, in which 25 children had varicella (68% were vaccinated). Disease was milder among vaccinated children.[94] This led to the recommendation by the Advisory Committee on Immunization Practices (ACIP) in 2006 for a universal two-dose varicella vaccine schedule. The first dose is given when the child is 12 to 15 months of age, and a second dose is given at 4 to 6 years of age.[42]

Approximately 10 to 15 percent of the time, a child may have a vesicular rash at the site of vaccination, 5 to 26 days after receiving the immunization. If this does occur without further spread of rash or systemic symptoms, the child may attend child care with the lesions covered.[13] A child with chickenpox disease should be excluded from the child care setting until all lesions are scabbed over and the child is able to participate in activities.

Measles

Measles (rubeola) is a highly contagious respiratory infection. After many years of decline, it again reached epidemic proportions in impoverished and medically underserved inner-city areas in the United States between 1989 and 1992. Although susceptibility to measles virus infection occurs when maternal antibody wanes, the peak age group for measles in the preimmunization era was children between 5 and 9 years old. More recently, outbreaks have involved preschool-age children, thus setting the stage for outbreaks in daycare facilities.

Measles virus is spread by droplets, hand transmission, and the airborne route. The illness usually is moderate to severe; high fever and prominent respiratory symptoms (cough and coryza) and conjunctivitis are present for several days before onset of the rash. Diarrhea occasionally may be a prominent feature. After the rash erupts, the fever and respiratory symptoms persist for several more days. Pneumonia and encephalitis are complications of measles virus infection; each occurs at an incidence of 1 per 1000 cases.

Since the year 2000, measles has no longer been considered endemic in the United States. However, measles cases continue to be reported each year; there were 222 measles cases reported in 2011. Of these cases, 200 were linked to importation by travelers or to one of 17 outbreaks. Of the infected youth (younger than 19 years) who were eligible for vaccination, 50 percent were unvaccinated because of religious, philosophical, or personal objection.[48]

Measles is prevented effectively by immunization. Current recommendations are to immunize twice, once when the child is between 12 and 15 months of age and

again at 4 to 6 years of age. For exposed, susceptible children, vaccination is recommended with MMR vaccine within 72 hours of exposure. During an outbreak, vaccine may be given to children 6 to 11 months of age. However, a child who receives measles vaccine before 1 year of age must still receive the vaccine at 12 to 15 months of age; the first dose is not counted toward the two required for full protection. Immune globulin can be given within 6 days to an exposed, susceptible individual for whom the live viral vaccine is contraindicated. This includes infants younger than 12 months and immunocompromised individuals.[15] Children with measles and any exposed unimmunized children should be excluded from the group care setting until at least 2 weeks after the onset of rash in the last case of measles.[13]

Rubella

Rubella, another exanthematous disease of childhood, is much milder than rubeola but attacks a similar age group. Like measles, until recently, rubella had been nearly eradicated by routine universal immunization with MMR vaccine.

Rubella is characterized clinically by mild fever, lymphadenopathy (postauricular and occipital), and rash. The illness is difficult to distinguish from other viral exanthems. Infection may be completely asymptomatic. Children with documented rubella should be excluded from daycare until 7 days after the onset of illness.

If rubella is contracted during the first or early second trimester of pregnancy, a severe fetal infection resulting in microcephaly, deafness, congenital heart defects, eye disorders, and psychomotor retardation may result. Acquisition of infection during pregnancy may be a potential hazard for daycare personnel or mothers of children who attend daycare if an outbreak of rubella occurs in the daycare setting. In a large outbreak of rubella in Nebraska, 14 children (9 of whom were younger than 12 months) and 2 parents acquired their infection in a daycare center.[68]

The incidence of congenital rubella syndrome can be minimized by appropriate immunization of preschoolers and personnel. Any child or personnel with rubella infection (not congenital) should be excluded from the group child care setting until 7 days after the onset of rash. Any exposed, unimmunized or underimmunized children should be excluded from a group setting until they are immunized or determined by public health officials to be noninfectious if they do not receive immunization. A child with congenital rubella syndrome is considered contagious until at least 1 year of age unless two cultures of clinical specimens obtained 1 month apart are negative for rubella virus after 3 months of age.[15]

Pertussis

Pertussis, or whooping cough, is a highly communicable respiratory disease caused by *Bordetella pertussis*. The attack rate and severity of disease are highest in the first year of life. The illness classically is divided into three phases: catarrhal, paroxysmal, and convalescent. In the first stage, the child has no fever but has symptoms, primarily rhinorrhea and a cough. When the nasal symptoms resolve, however, the cough becomes and remains prominent for many weeks. The cough is characterized by paroxysms that are followed by an inspiratory effort (whoop) or leave the child exhausted and occasionally apneic. The convalescent stage is the many weeks necessary for complete recovery. Infected children younger than 1 month are at greatest risk for significant morbidity and mortality. Treatment with a macrolide is effective in decreasing the shedding of organisms, but it does not alter the course of the disease.

Complete immunization with a five-dose series of acellular pertussis vaccine is effective in preventing most cases of pertussis.[54] However, pertussis continues to cause disease in vaccinated and unvaccinated persons, with peaks in incidence occurring every few years. In 2004, there was a significant national increase in pertussis cases nationwide. In 2012, a pertussis epidemic occurred in the state of Washington, with highest incidence among infants younger than 1 year and children aged 10 to 14 years.[47] Similar age trends were seen nationwide in the many geographic areas affected by the epidemic.

After a person has been exposed to a case of pertussis, erythromycin, clarithromycin, and azithromycin provide effective prophylaxis and are first-line drugs, despite their negligible clinical effect after the paroxysmal stage begins. Trimethoprim-sulfamethoxazole is an alternative in a person older than 2 months who is unable to tolerate a macrolide or has macrolide-resistant pertussis documented. Prophylaxis is recommended for exposure in child care. If appropriate, booster doses of acellular diphtheria-tetanus-pertussis vaccine should be given to exposed children in a daycare or household setting. A child who has pertussis or has been exposed to a case of pertussis and is symptomatic should be excluded from daycare until 5 days of an appropriate course of a macrolide (azithromycin or erythromycin) has been received.[15] If no treatment is received, exclusion is for 21 days after cough onset. Immunization status should be updated if a person is underimmunized. Child care staff are an appropriate target group for receipt of a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine licensed as a single booster vaccine for persons older than 10 years with no upper age limit.[46]

Poliomyelitis

Poliovirus is an enterovirus that now rarely causes disease in the United States. Although most infections with poliovirus are subclinical, in the preimmunization era, polio was the major cause of acquired paralytic disease, especially in older children and young adults. In some developing countries, it remains a major health problem.

Poliomyelitis is prevented effectively by use of either the live oral poliovirus vaccine or the inactivated, enhanced-potency parenteral vaccine (IPV).[182] The ACIP of the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics recommend a four-dose all-IPV vaccine schedule for routine immunization of all infants and children in the United States.[15]

Mumps

Mumps is a relatively benign infection of childhood that often is asymptomatic. The most prominent clinical feature is parotitis. On occasion, a clinically significant central nervous system infection causes unilateral sensorineural deafness. This infection had been dramatically reduced by widespread use of the MMR vaccine. However, in the past decade, large outbreaks have occurred in the United States. In 2006, an outbreak occurred primarily among vaccinated young adults in the Midwest,[70] and in 2009, an outbreak occurred primarily among vaccinated school-age children in a religious community in New York and New Jersey.[43] Children with mumps should be excluded from the group child care setting until 5 days after the onset of parotid swelling.[15]

Rotavirus Infection

Before the introduction of rotavirus vaccine for the immunization of infants in 2006, rotavirus was the most common identifiable infectious cause of gastroenteritis leading to hospitalization in young children.[30,72,120,156,235] It accounted for more than 25 percent of cases of diarrhea in the United States, and it is an important cause of diarrhea in developing countries as well, contributing substantially to the worldwide mortality figures for gastroenteritis.

A low inoculum of rotavirus is needed to cause infection. The virus can be recovered from asymptomatic hosts, especially neonates and infants.[51] It is shed in large numbers in the stool of symptomatic patients, thereby contributing to the high prevalence of the virus on environmental surfaces during outbreaks.[237] Viral shedding occurs both before and after symptoms have appeared.[180] Most illnesses caused by rotavirus occur in the cooler months in temperate climates, but they occur year-round in tropical areas. The peak attack rate is in the 6- to 24-month-old age group. After a brief incubation period of 2 to 3 days, patients may have prodromal respiratory symptoms (coryza and cough) and then varying combinations of vomiting, diarrhea, and low-grade fever that last 3 to 5 days. The range of severity is broad, and dehydration occasionally may be profound. Before the introduction of vaccine, many outbreaks were reported in group child care settings.[23,170,180,189] In prospective studies of diarrheal illness in children attending daycare, rotavirus was implicated in 6 to 24 percent of cases of gastroenteritis[22,23,120,219] as well as in 20 to 40 percent of outbreaks.[23]

Rotavirus cannot be cultivated easily in tissue culture in a viral diagnostic laboratory. The diagnosis is made with an antigen detection method on a stool specimen. Treatment is supportive, and exclusion from daycare is recommended until the diarrhea resolves.

In early 2006, a bovine rotavirus–based pentavalent vaccine was licensed for use in U.S. infants. Three doses of the vaccine are given orally at 2, 4, and 6 months of age.[16] In 2008, a monovalent attenuated human rotavirus was licensed for a two-dose schedule given orally at 2 and 4 months. Both have been shown to be effective in preventing rotavirus infection of any severity.[31,33,73,209]

Hepatitis A Virus

Before the institution of universal immunization of young children, HAV, an enterovirus, was a common cause of acute hepatitis in children. Like other enteric pathogens, this organism is transmitted by the fecal-oral route. Manifestations of infection vary remarkably according to age. In young children (younger than 6 years), infection with HAV may be entirely asymptomatic or associated with relatively mild and nonspecific symptoms, such as low-grade fever, anorexia, nausea, vomiting, and diarrhea in 30 percent of patients. Jaundice, a more specific marker of liver disease, occurs in less than 10 percent of children younger than 6 years.[99] In contrast, adults with hepatitis A often are icteric in conjunction with other gastrointestinal symptoms. Infection, when symptomatic, usually lasts several weeks but occasionally can become protracted.

Transmission is primarily by person-to-person spread, but fomites may play an important role because the organism can persist and remain infective in the dried state for months.[157] HAV is shed in high density in the stool of infected persons from 2 weeks before until 1 week after the onset of clinical symptoms. The diagnosis usually is made by detecting serologic evidence of marker antibodies against HAV (immunoglobulin M anti-HAV). Treatment is symptomatic. Prevention of illness in contacts can be accomplished with intramuscular immune serum globulin and with hepatitis A vaccine.[15] Children and adults (especially food handlers) with hepatitis A disease should be excluded from the group child care setting until 1 week after the onset of illness.[15]

Hepatitis A vaccine was initially recommended for individuals in high-risk situations (e.g., travel, immunocompromised status) in 1996. Since the recommendation for universal vaccination of children 12 to 23 months of age, there has been a significant reduction in the incidence of acute hepatitis A disease.[41] Recent clusters of infection have been reported among close contacts of asymptomatic, newly arrived international adoptees from countries with high rates of hepatitis A.[87] The American Academy of Pediatrics, the ACIP, and the CDC have recently recommended vaccination of close contacts of internationally adopted children at risk for hepatitis A, including parents and babysitters.[17]

Hepatitis B Virus

HBV is a DNA-containing virus that causes infections with a wide range of clinical manifestations from asymptomatic seroconversion to fatal hepatitis. Infection is more likely to be asymptomatic in children than in adults.[158] Common symptoms include fever, fatigue, anorexia, malaise, and jaundice. Other gastrointestinal symptoms, such as nausea, vomiting, and diarrhea, may be prominent. Joint symptoms (arthritis and arthralgias) and cutaneous lesions (papular acrodermatitis) may be noted early in the course of the illness.

The most common modes of transmission of HBV in adults are contact with blood and sexual activity. Young children usually acquire infection with HBV by vertical transmission from their mother at delivery. The maternal

infection may be acute or chronic. Infection acquired vertically by an infant usually is asymptomatic, but it leads to chronic carriage of hepatitis B surface antigen in most cases. With increasing immigration and adoption of infants from HBV-endemic areas, more HBV carrier children will be identified.[112] It is important to screen children from areas where the prevalence of hepatitis B is more than 2% as they arrive to the United States.

Transmission of HBV within the daycare setting is rare but has been reported.[69,74,202] In one case, the probable source was a bite by a child who was a carrier of HBV.[202] In another, a child care worker with chapped hands was exposed to the blood of a child who was an HBV carrier.[74] The third case involved an aggressive 21-month-old child with weeping dermatitis and a history of biting other children. Other investigations failed to demonstrate transmission in daycare facilities despite long-term contact, including one situation with a high potential for blood exposure.[203]

Implementation of the current recommendation to screen all pregnant women for HBV and to undertake universal immunization against hepatitis B in infancy is the most effective way to prevent the spread of this infection. In the United States, there has been a steady increase during the past decade in the uptake of vaccination of infants at birth, regardless of maternal hepatitis B status. Approximately 70 percent of infants received a birth dose in 2007.[243] Infants born to mothers positive for hepatitis B surface antigen are recommended to receive hepatitis B immune globulin in addition to the vaccine. The incidence of acute hepatitis B disease in youth younger than 19 years has decreased by 98 percent.[15] Because of the low risk of transmission within the group child care setting, the American Academy of Pediatrics, the American Public Health Association, and the CDC do not recommend exclusion of HBV-infected children from child care or HBV screening of children as a criterion for entry. Exclusion of any child is appropriate if the child has weeping sores that cannot be covered or uncontrolled bleeding problems.

CONTROL OF INFECTIONS IN OUT-OF-HOME CHILD CARE

The American Academy of Pediatrics, the American Public Health Association, and the National Resource Center for Health and Safety in Child Care and Early Education have developed consensus guidelines on planning and practices in child care that promote the health of children, including practices that prevent and control the spread of infection. There is information on collecting and maintaining health records of children and staff, planning the physical space of the facility, cleaning and disinfecting spaces, educating staff and families on recognizing potentially infectious illnesses, and establishing exclusion policies for specific infections.[14]

Written Policies

Each child care facility should have written policies for preventing and managing child and staff illness. This includes having written procedures for hand washing and hand hygiene; personal hygiene policies; environmental sanitation policies and procedures; and policies for collecting, filing, and updating health and immunization records of children and staff.

Environment and Physical Plant Characteristics

In the planning of child care facilities, space and equipment needs that minimize the risk for transmission of infectious agents must be considered. Because fecal contamination is related strongly and inversely to age, having physical premises large enough to separate children younger than 3 years from older children is important. The food handling and food storage areas should be separated from the toileting and diapering space. When tables in the play area are used for food, they must be sanitized before food service. Because contamination of hands is the most critical factor in transmission of infection, hand washing facilities must be easily available to staff and children. Such facilities are especially important in the diaper-changing/toileting and food preparation areas, and separate sinks should be used in each of these areas. The hand washing sinks should be made of nonporous materials and preferably be hands free and in easy reach of soap and towel dispensers.

Because fecal-contaminated surfaces are major vehicles for the spread of enteric infections, particular care must be taken in planning the space and selecting equipment for diaper-changing and toileting activities. When materials are selected, the choice should be based on durability and ease of cleaning and disinfecting. Diaper-changing tables should be made of nonporous materials, without cracks or crevices, that can be cleaned and disinfected easily. They should be cleaned and disinfected after each use. A hands-free, plastic-lined container should be used for disposal of soiled diapers and placed within easy reach of the changing table. The toddler area should be equipped with training toilets and junior-sized toilets with appropriate steps. The use of potty chairs is strongly discouraged. If they are used, they should be constructed of easily cleaned nonporous materials, used only in the bathroom area, cleaned in a utility sink designated for potty chairs, and disinfected after each use (both chair and sink).[14]

Immunization and Screening of Children and Staff

Primary immunizations in infants and toddlers have greatly reduced the number of many of the communicable illnesses that were easily transmitted among children in closed settings decades ago. Currently, the 14 vaccine-preventable diseases for a preschool child are diphtheria, tetanus, pertussis, poliomyelitis, influenza, measles, mumps, rubella, varicella, rotavirus infection, *H. influenzae* infection, *S. pneumoniae* disease, hepatitis A, and hepatitis B. Studies have shown that children who attend registered child care facilities are more likely to be up-to-date in their immunizations than are children cared for at home.[119] Laws requiring age-appropriate

vaccination of children attending licensed child daycare programs exist in almost all states.

Employees and volunteers should have a health assessment before initiating work with children. This includes updating immunizations or documenting immunity to infections such as hepatitis A and B, measles, mumps, rubella, varicella, diphtheria, tetanus, polio, pertussis (to include one dose of acellular pertussis), and influenza. Recommendations for vaccination of children and adults are updated regularly by the ACIP.[7] Staff should receive annual influenza vaccinations, especially as young infants are a most vulnerable population for significant morbidity with influenza illness.

Before initiating work in a child care setting, adult and adolescent staff should be screened for tuberculosis by skin testing or a blood interferon-γ release assay. If the initial screening result is negative, those at risk should have annual tuberculosis testing. If the result is positive, a chest radiograph should be performed, and the staff member should be evaluated and cleared by a health care provider or public health official before beginning child care activities.[14]

Education

An integral part of the control of infection within a daycare center is education of staff and families. The staff must understand the general principles of transmission and control of infections. Education before job placement and frequent in-service trainings reinforce the importance of some basic techniques, especially hand hygiene. Supervision is essential to ensure compliance with policies.[141]

Parents should be educated about recognition of illness, especially illnesses for which the child receives the best care at home. The rationale and importance of compliance with daycare center rules should be emphasized. The child care program should inform parents of the need to share information about communicable illnesses in the child or a family member.

Hygienic Standards and Interventions

The key factor in prevention of disease in the child care setting is maintenance of optimal hygienic standards based on recognized mechanisms of transmission of infection. Hand hygiene is considered the single most important preventive measure[28,101,141,179,193] in recognition of the finding that both respiratory and enteric pathogens are spread by contaminated hands. Hand hygiene includes hand washing and the use of alcohol-based sanitizers.

Two studies showed a modest benefit of increased attention to hand washing in preventing respiratory tract infections in children younger than 2 years and in preventing episodes of diarrhea in children older than 2 years.[187,188] Two other studies have evaluated the role of alcohol-based sanitizers in the homes of children in out-of-home child care in reducing the secondary spread of illness. One demonstrated a reduction in gastrointestinal illness among family members,[193] and the other showed a reduction in respiratory illnesses.[146] Applicability to the child care environment also has been evaluated as part of several multipronged interventional programs.[125] A meta-analysis of studies evaluating the effect of hand hygiene interventions on reducing respiratory and gastrointestinal illness in community settings showed interventions that involved hand hygiene education plus the use of ordinary soaps had the greatest decrease in gastrointestinal and respiratory illnesses. The majority of studies evaluated were performed in child care centers and involved children younger than 5 years. No significant differences in benefits were noted with the use of alcohol-based sanitizers or antibacterial soaps.[8]

Exclusion Policy

The use of exclusion policies for specific infectious illnesses reflects the understanding that when children have moderate to severe illnesses, they may require more individualized care than available staff can provide, and their continued presence in the child care setting may expose more children and staff to infection. Children with enteric illnesses shed infectious agents in their stool. When stool is not easily contained in a diaper or toilet-trained children have accidental stooling due to diarrhea, transmissibility of infection increases significantly. Similarly, respiratory agents shed in secretions are readily transmissible through coughing, sneezing, or contamination of hands or environmental surfaces.

The indications for exclusion of children from child care and return to care vary on the basis of the infection. In some cases, children known to have highly infectious illnesses should not be allowed to attend daycare until treatment is initiated (e.g., group A streptococcal infections) or the symptoms have resolved (e.g., diarrhea caused by *Shigella*, rotavirus, or *Giardia*) or until transmissibility has waned, as in pertussis, varicella, measles, and mumps. In addition, there are certain symptom complexes for which children should be excluded if the specific pathogen or the contagiousness of their illness is unknown (e.g., if a child has a high fever and a rash or diarrhea of unknown etiology). A complete list of recommendations for exclusion is presented in Table 247-5.

There are some children attending group child care who remain unimmunized or underimmunized because of either contraindications for health reasons (e.g., immunocompromised state) or exemptions for a family's philosophical, religious, or personal beliefs. In the event of an outbreak of a vaccine-preventable disease (such as measles), these children should be excluded from child care until return is indicated by disease-specific guidelines.[13]

There are conditions that do not necessarily require exclusion from child care. These include asymptomatic excretion of an enteropathogen, purulent or nonpurulent conjunctivitis, a rash without a fever or behavioral change, CMV infection, the carrier state of HBV infection, HIV infection, and parvovirus B19 infection in an immunocompetent host. For many infections, the highest risk of transmission of disease occurs before the appearance of recognizable symptoms. Once illness occurs, other children already have been exposed, and exclusion is a less effective strategy. For this reason, exclusion has not been shown to be successful in reducing the frequency of viral upper respiratory tract infections.

TABLE 247-5 **Recommendations for Temporary Exclusion from Child Care**

Symptom Complexes	Specific Etiology	Temporarily Exclude?	If Excluded, Readmit When
Illness that prevents child from participating comfortably in activities		Yes	Exclusion criteria are resolved and child is able to participate without compromising staff's ability to care for other children
Illness that results in a greater need for care than the program staff can provide without compromising their ability to care for other children		Yes	
Other health conditions that may indicate severe illness (e.g., fever, lethargy, persistent crying, difficulty breathing)		Yes	
Cold symptoms: runny nose, scratchy throat, coughing, sneezing, watery eyes, fever	Adenovirus Coxsackievirus Enterovirus Parainfluenza virus Respiratory syncytial virus Rhinovirus Coronavirus Influenza	No, unless: Fever accompanied by behavior change Looks or acts very ill Difficulty breathing Blood red or purple rash not associated with injury	
Conjunctivitis (pinkeye)	Bacterial Viral	No, unless child meets other exclusion criteria	For bacterial conjunctivitis: once parent has discussed with health professional Antibiotics may or may not be prescribed Exclusion criteria are resolved
Fever		No, unless: Behavior change Unable to participate Care would compromise staff's ability to care for other children	Able to participate Exclusion criteria are resolved
Diarrhea Frequent loose or watery stools compared with normal pattern Abdominal cramps Fever Sometimes accompanied by vomiting		Yes, if: Stool is not contained in the diaper Diarrhea is causing "accidents for toilet-trained children" Stool frequency exceeds 2 or more stools above normal for that child Blood or mucus in stool, abnormal color of stool Dry mouth, no tears or no urine output in 8 hours Jaundice	Diapered children have their stool contained by the diaper Toilet-trained children do not have toileting accidents Able to participate without compromising staff's ability to care for them
	E. coli O157:H7	As above	As above Test results from 2 consecutive stool cultures taken 24 hours apart are negative for *E. coli* O157:H7

Continued on following page

TABLE 247-5 **Recommendations for Temporary Exclusion from Child Care** (Continued)

Symptom Complexes	Specific Etiology	Temporarily Exclude?	If Excluded, Readmit When
	Salmonella	As above	As above For *S. typhi*, health professional must clear child for readmission and children (<5 years) must have 3 negative stool cultures
	Shigella	As above	As above When infected child is treated and 2 stool cultures taken 24 hours apart are negative Health professional must clear child
Mouth sores	Herpes simplex virus Enterovirus (e.g., coxsackievirus)	No, unless drooling steadily related to mouth sores	Able to participate Exclusion criteria are resolved
	Hepatitis A	Yes, children and staff, especially food handlers	One week after illness onset and contacts have received vaccine or immune globulin as recommended
	Impetigo (*S. pyogenes, S. aureus*)	Yes, wash and cover sores Exclude at end of day	When topical, oral, or systemic antibiotics are started If sores can be covered and kept dry
	Head lice	Yes, at end of day	After receiving recommended treatment
	Measles	Yes, ill child and unimmunized contacts not immunized within 72 hours of exposure	Until 4 days after rash onset Unimmunized contacts at least 2 weeks after onset of rash in last case of measles
	Mumps	Yes, ill child and unimmunized contacts during outbreak	Until 5 days after onset of swelling Unimmunized contacts—until health department determines safe return
	Pertussis	Yes	After 5 days of appropriate antibiotic treatment
	Scabies	Yes	Until treatment is completed
	Staphylococcal skin infection (MRSA)	No; open or draining boils or abscesses should be covered	
	Streptococcal pharyngitis	Yes	After 24 hours of antibiotic treatment
	Tuberculosis	Yes	When local health officials determine child to be noninfectious to others
	Varicella	Yes	When all blisters have scabs

Modified from American Academy of Pediatrics. *Managing infectious diseases in child care and schools: a quick reference guide.* 2nd ed. Elk Grove Village, Ill: American Academy of Pediatrics; 2009.

Prophylaxis of Close Contacts

Prophylaxis is a strategy that may be useful in the management of some infections that occur in child care centers. For example, if a child has had invasive disease caused by *N. meningitidis*, rifampin prophylaxis for all child care contacts may prevent secondary or associated cases. If a child has pertussis, exposed children may be protected by a booster immunization, if appropriate, and administration of erythromycin or azithromycin for prophylaxis.

During community epidemics, vaccination can be used as a strategy to prevent secondary infections. For example, immunization with MMR vaccine is successful in terminating epidemics of measles in elementary or high schools. Varicella vaccine also can be used throughout a community and up to 3 days after exposure to curtail the spread of disease. Hepatitis A vaccine is an appropriate intervention for controlling an outbreak of hepatitis A in child care centers and other settings.[124]

CHAPTER 248

Animal and Human Bites

Morven S. Edwards

Many children delight in teasing dogs, and without caution go too near them, by which they get miserably torn and mangled. … What these boys had been doing to enrage the dog we cannot tell, but suspect they had been tormenting him in some way, thinking that as he was chained he could not injure them. But they were mistaken in this, and one of them is likely to be bitten very severely.[6]

AUTHOR UNKNOWN, 1830

HISTORICAL ASPECTS

The consequences to children of bites resulting from provoking dogs, as noted in the opening quotation, were of concern in the 19th century just as they are today.[23] In early reports, infected bite wounds were noted to contain fusiform bacilli and spirochetal organisms.[95] We now appreciate that a vast number of aerobic and anaerobic organisms composing the normal flora of the biting animal's mouth are potential bite wound pathogens. Human bites have been recorded since the biblical era and currently are a common cause of serious medical and surgical diseases. They are the third most frequent type of bite after dog and cat bites. Reports of secondary infection occurring after a human bite in children have been noted in the United States since at least 1910.[64]

The importance of débridement and drainage in treatment of infected bite wounds was understood in the preantibiotic era, but these infections carried a high morbidity rate.[93] In a report from 1936, amputation was required in one third of cases in which treatment was delayed for 24 hours or longer.[118] Adjuncts to cleansing, such as electrocauterization and even radiation therapy, were used in efforts to prevent or to treat infection, but not until the introduction of penicillin was the outcome of bite wound infections improved over that achieved by symptomatic therapy alone.[93]

EPIDEMIOLOGY

More than 100 million cats and dogs are kept as pets in the United States.[47] The estimated annual incidence is 1 to 2 million dog bites, 400,000 cat bites, 250,000 human bites, and 45,000 snake bites.[48] Rabbits, skunks, squirrels, horses, rats, hogs, and monkeys cause at least 1 percent of bite injuries. Unprovoked pet ferret attacks have caused severe facial injuries.[34] Taken together, however, bites from nondomestic animals, generally thought to pose a higher risk for transmission of rabies, constitute less than 1 percent of reported bite wounds. The right arm is bitten most frequently, presumably because of defensive attempts by victims using their dominant arm. At least three quarters of bites are located on extremities. Facial bites represent only 10 percent of the total, but two thirds of them are sustained by children younger than 10 years.

Children are the most common victims of animal bites. From one half to three fourths of dog bites are reported in persons younger than 20 years. Dog bites cost more than $1 billion per year in the United States.[89] The peak incidence is in children 5 to 9 years of age.[97] Many bites do not require a visit to the physician and are not reported. Up to 1 percent of all pediatric emergency department visits during the summer months are for treatment of animal bites.[28,66] Approximately 5 percent of children requiring medical care for dog bite require hospital admission.[25] Most bites occur in late afternoon and early evening hours. Boys sustain dog bites twice as often as do girls, but girls are bitten more frequently by cats.

Large dogs account for most animal bites and are implicated most frequently in bites with a fatal outcome. Ten to 20 fatal human attacks occur yearly in the United States. At least 25 breeds of dogs were implicated in 238 fatalities from dog bites during the past 25 years.[104] The most common breeds included pit bull terriers (51%) and Rottweilers (9%) in one series of 551 pediatric dog bite injuries.[69] These animals can exert a biting force of 1500 psi, several times that of a German shepherd. The severity of wounds inflicted by pit bull breeds also is due to their tendency to inflict multiple bites and to bite and grind their molars into tissue. In one study, 94 percent of injuries caused by pit bulls were the consequence of unprovoked attacks.[9] In most instances (75%), the dog's owner is known by the victim, although only a small percentage of bites are caused by a family-owned dog. Stray dogs account for 10 percent of bites inflicted. When the circumstances are known, most mammalian bites are provoked, although the victim may not have agitated the animal intentionally.[109]

Infection is a common complication of animal bites. Between 3 and 20 percent of dog bites and 20 to 50 percent of cat bites for which medical care is sought become infected.[26,68] With the exception of monkey bites,

which have a high infection rate, infection seldom develops after bites by other mammals. Factors influencing the risk for development of infection include the patient's age, type and location of the wound, and length of time that transpires between the bite and initiation of treatment. Wounds of the hand are more likely to become infected than are those of the arm, leg, or face. Puncture wounds more often become infected than do lacerations, superficial wounds, or wounds with skin and soft tissue defects. Infection is likely to develop when wounds are repaired surgically or when care is delayed more than 24 hours after injury.

The incidence of infection after human bites is estimated to be 10 to 30 percent. Because of the typically superficial nature of human bite wound injuries in children, the infection rate in children is estimated to be approximately 10 percent. Human bites have their peak incidence in the spring and early summer[80] and on Saturdays, especially for the adolescent age group. Alcohol and drug abuse may play roles in some of these instances. Bites occur more commonly in males than in females except for the 15- to 20-year-old age groups, in which females are bitten more frequently.[21,80] Human bites occur most often in men 20 to 25 years of age. Most bites in teenagers are associated with aggressive behavior. Among 322 children who suffered human bites, 21 percent were younger than 5 years, 21 percent were 5 to 10 years of age, and 58 percent were older than 10 years.

Biting is a common occurrence in the child care center setting, for which it is the third most frequently reported injury. The incidence peaks in midmorning and during the early school year in September. Toddlers from 13 to 30 months of age are bitten more often than are infants and other preschoolers,[110] and boys are bitten more frequently than are girls.[44,111] Bites account for 3 and 6 percent of reported injuries in boys and girls, respectively,[39] and may be self-inflicted in many cases.[21] Approximately 50 percent of all children enrolled in daycare suffer bite wounds, with a rate of 3.9 bites per child per year in general but 9.4 bites per male child per year for full-time enrollees.[44,108] Most of these bites are minor and do not break the skin. A higher proportion of bites in younger children (such as preschoolers) are to the face, whereas most bites in adolescents are on the upper extremities and hands.

Paronychial infections are not actual bites, but when infection occurs, it is related to contamination by oral flora when children bite or suck their fingers. Brook[17] noted children from 2 to 9 years of age (mean age, 5 years 8 months) who were treated at a children's hospital for paronychial infection and reported the bacteriologic and clinical findings of these infections.

Bites as harbingers or signs of child abuse are noted more commonly in the 0- to 4-year-old age group[93]; the age of the abusing parents was younger than 20 years for mothers and younger than 22 years for fathers. An attempt should be made to identify the biter and measure distances between circular bite marks to ascertain the spread. In addition, biting children may have learned this behavior from abusive adults and may themselves be victims of human bites.

MICROBIOLOGY

The oral flora of the biting animal, rather than skin flora of the victim, is the source of most isolates from bite wounds, but both can be sources for infection.[1] Infections usually are polymicrobial and contain mixed aerobic-anaerobic isolates. Table 248-1 enumerates bacterial isolates from the wounds of 50 patients with dog bites and 57 patients with cat bites that were infected at the time of arrival at an emergency department for care.[113] A median of five bacterial isolates were found per culture. Slightly more than half of the wounds yielded both aerobes and anaerobes, and anaerobes alone were isolated from slightly more than one third of the wounds. *Pasteurella* spp. were the isolates most frequently found in dog and cat bites (50% and 75%, respectively), with *Pasteurella canis* being isolated most commonly from dog bites and *Pasteurella multocida* subspecies *multocida* and *septica* the most common isolates from cat bites. *Pasteurella*

carrier rates are as high as 66 percent for dogs and 90 percent for cats, so one is not surprised that this organism is associated so commonly with bite wound infections. Infection has occurred as a consequence of bites by large cats, including lions,[18] cougars,[71] and tigers,[20] as well as by house cats. The type of wound commonly inflicted (i.e., puncture by cats versus laceration by dogs) might explain the species-specific disparity in infection rates.

Other aerobic agents commonly isolated from infected dog or cat bites include streptococci, staphylococci, *Moraxella*, *Neisseria*, and corynebacteria. Although streptococci often are β-hemolytic, *Streptococcus pyogenes* was isolated from only 12 percent of dog bites and none of the infected cat bites in one large series.[113] *Staphylococcus aureus* was isolated frequently from infected dog bites but infrequently from cat bite wounds. Species such as *Capnocytophaga canimorsus* and *Neisseria weaveri*, previously classified under the Centers for Disease Control and Prevention alphanumeric system, are notable because infections in association with these species have occurred in splenectomized persons or those with immunocompromising conditions.[4,76]

Animal bites are implicated as a vehicle for transmission of a number of systemic infectious diseases caused by viruses, fungi, and mycobacteria in addition to bacteria (Table 248-2).[96] Transmission of such unusual pathogens as orf virus, *Pseudallescheria boydii*, or *Mycobacterium chelonae* by bites of a goat, dog, or ferret, respectively, has been described.[65,74,101] Cats can transmit such unusual infections as diphtheria, coccidioidomycosis, and tularemia.[13,42,116] Tularemia can also be transmitted by the bite of such diverse species as wild boar, coyote, hog, lamb, muskrat, opossum, raccoon, rat, skunk, squirrel, snapping turtle, and weasel.[7,19,81]

The bacteriology of human bite wounds also reflects the human oral flora of the biter.[16,112] Human saliva and dental plaque can contain more than 42 different species of bacteria in concentrations of 10^8 colony-forming units per milliliter. Table 248-3 lists common human bite wound isolates and their relative frequency of isolation.[12,16,57,86,112] α-Hemolytic streptococci, especially *Streptococcus anginosus*, are the most frequent isolates. Other common bacterial isolates include *Streptococcus pyogenes*, *Staphylococcus aureus*, *Haemophilus* spp., *Eikenella corrodens*, and oral anaerobes, especially *Fusobacterium*, *Prevotella*, *Veillonella*, and *Peptostreptococcus* spp. Cultures of virtually all infected bite wounds grow bacterial pathogens; wound cultures of patients who initially are seen less than 8 hours after incurring an injury, before the development of clinical infection, yield potential bacterial pathogens in 85 percent of cases.[47] The bacteriology of early-treated, colonized wounds is remarkably similar to the bacteria isolated from wounds evaluated later with established infection. The average bite wound yields between 3.4 and 5.4 bacterial isolates per wound, including 1.7 to 2.4 aerobes and 1.7 to 3 anaerobes. Anaerobes are isolated from more than 50 percent of human bite wounds, almost always in mixed culture with aerobes, and they are associated more often with more serious infections, amputation, and the presence of abscesses.[52,112] Many of the anaerobes isolated from human bite wounds, especially *Prevotella* and *Porphyromonas* spp., are β-lactamase producers.[17,112]

E. corrodens, a capnophilic, gram-negative rod that is part of the normal human oral flora, is an important pathogen in clenched-fist injuries.[49] It has an unusual antimicrobial susceptibility pattern in that it is susceptible to penicillin but resistant to first-generation cephalosporins, β-lactamase–stable penicillins (such as oxacillin), and erythromycin.[51] When it is unrecognized or treated with the incorrect antibiotic, *E. corrodens* has been associated with therapeutic failure. Usually isolated in mixed culture, it may be missed by microbiologists because of its slow growth characteristics and overgrowth of other bacterial colonies. *E. corrodens* produces a small colony that "pits" or "corrodes" the agar surface and has a light yellow pigment and an odor like that of hypochlorite bleach.

The bacteriology of paronychial infections is similar to that of other human bite infections, except that aerobes and anaerobes each have been isolated in pure culture in some cases. Brook[17] found a total of 3.6 isolates per specimen: 1.4 aerobes, 2 anaerobes, and 0.2 *Candida albicans;* β-lactamase–producing organisms, including isolates of *Prevotella melaninogenica* and *Prevotella oralis*, were found in 45 percent of the wounds.

In addition to oral bacterial infection, human bites have been associated with viral infections, such as those caused by herpes simplex virus,[40,83] cytomegalovirus,[83] hepatitis B virus,[26,63] hepatitis C virus,[32] and possibly human immunodeficiency virus (HIV),[5,70,106] as well as syphilis,[35] tuberculosis,[47] actinomycosis,[14] and tetanus[85] (Table 248-4).

concerned with prophylaxis or surgical repair. Findings suggestive of wound infection include localized swelling, erythema, and pain with or without serosanguineous or purulent drainage (Fig. 248-1). The clinical findings vary with the infecting organism, site of injury, and type of bite. The jaws and teeth of dogs are likely to produce multiple puncture wounds as well as jagged lacerations with devitalized tissue. These lesions can be associated with depressed skull fractures, sometimes in more than one cranial region. Puncture wounds, particularly those inflicted by cat bites, often are deceptively innocuous. Inoculation of organisms deep into poorly vascularized areas, such as tendon sheaths, fascia, joints, and bones, is likely to result in an infected wound.

Synovitis
Tendinitis, tenosynovitis

The characteristic findings of *P. multocida* infection include a rapid onset of intense pain, swelling, and erythema, often within hours after injury. Cellulitis is usually evident within 24 to 36 hours after the bite. Despite these intense local symptoms, patients generally are afebrile, and less than 20 percent have lymphangitis and regional adenitis. Patients with wound infection caused by staphylococci or streptococci usually experience less intense pain, have a delay between injury and the onset of symptoms of days rather than hours, and may have a more diffuse, less fiery cellulitis. Gas in tissues of the forearm clinically suggestive of clostridial gas gangrene has occurred in infections caused by *Streptococcus anginosus* and *Streptococcus mutans* after horse bite lacerations.[82] Wound infection clinically resembling that caused by *P. multocida* from which the related but more unusual gram-negative rod *Actinobacillus lignieresii* was isolated has been reported in a child who sustained a facial bite by a horse.[27]

Some of the complications resulting from direct extension or generalized spread of infection caused by animal bites are summarized in Table 248-5. Tenosynovitis caused by *P. multocida* can be apparent within hours or can be manifested days to weeks after injury, when persistence of swelling, tenderness, or pain and a mass overlying the involved tendon sheath suggest the diagnosis. *Pasteurella* osteomyelitis that develops after a cat bite is characterized by pain, swelling, and tenderness over the involved bone.[67] When the periosteum has been entered, osteomyelitis can develop despite early administration of local and antibiotic treatment. Bites to the cranium occur with relative frequency in small children because their heads are at the level of the mouth of medium- to large-sized dogs. Complications of perforating cranial bites in children include compound depressed skull fractures, brain abscess, dural lacerations, and extensive intracerebral injuries, which can prove fatal.[2,18] Brain abscess and meningitis can occur as complications of these injuries.

In patients with systemic infections transmitted by animal bites, the incubation periods and clinical manifestations vary with the causative agent. For example, streptobacillary rat-bite fever occurs after an incubation period of less than 1 week, whereas spirillary rat-bite fever, or sodoku, has a 2-week asymptomatic interval after the bite. For many of the infections listed in Table 248-2,* the bite wound serves as the site of inoculation and has healed completely during the incubation period. For example, fatal encephalitis has resulted from the bite or scratch of a monkey that is actively shedding B virus *(Herpesvirus simiae)*. Institution of acyclovir treatment intravenously at the time of injury may abort progression of the disease.[90] Isolation of *Capnocytophaga canimorsus* is common among patients with splenectomy, alcoholism, and chronic lung disease.[94] The symptoms heralding the onset of systemic infections caused by animal bites are discussed in their respective chapters.

A high index of suspicion can be required to trace the infection to the animal source. For example, most cases of human plague in the United States result from bites by infected fleas, but contact with a domestic cat infected with *Yersinia pestis* can be the source of infection.[41] With tularemia, an ulcerative or pustular lesion develops at the bite site 4 to 7 days after injury and is associated with fever, chills, and painful regional adenopathy. In a case of *Mycobacterium marinum* infection that developed after a dolphin bite, one of several discrete fluctuant masses containing the isolate developed in an area just proximal to the original wound.[37] *Mycoplasma* has been implicated in "seal finger" from a seal skin, tooth, or claw injury, an infection characterized by severe pain and massive swelling and erythema 4 to 8 days after injury.[10] With cat-scratch disease caused by *Bartonella henselae*, a papule or pustule may be present at the original bite site when systemic signs develop. An ulceration at the site of a rodent bite has been described with sporotrichosis.[62]

Human bites can be categorized as those resulting in paronychial infection, occlusional bites, and clenched-fist injuries. Potential complications of human bites are noted in Table 248-6. Paronychia is an infection (inflammation) of the structures of the distal phalanx, either those surrounding the nail or the bone itself. Most are caused by finger sucking in younger children but may be caused by accidental biting. The area is red, tender, and swollen and may have some underlying purulence.

Most occlusional wounds are minor and require routine care with cleansing and bandaging. The infection rate after occlusional bite wounds is 10 to 30 percent, 87 percent of which may require hospitalization.[11] Wounds to the hand and with any edema or crush injury and those that involve a bone or a joint have a greater potential to become infected. Infections usually are manifested as cellulitis. If the child is treated early, these injuries rarely result in serious complications. These infections generally spread proximally and in less than 5 percent of cases have associated fever, lymphangitis, or lymphadenopathy. A malodorous discharge or abscess can be present if anaerobes are involved. Complications may be limited to skin defects when skin avulsion has occurred, but septic arthritis and osteomyelitis may develop if the joint or bone is involved.[58] In immunocompromised hosts, such as those with hematologic malignant disease or neutropenia, sepsis may occur. Amputation can be necessary as a result of the initial bite or as a result of serious chronic infection.[77] Tendon injury, primary nerve injury and tenosynovitis, compartment syndrome, and resultant secondary nerve damage can occur.[88]

Clenched-fist injuries, or "fight bites," are the most serious of human bite wounds and occur when the closed fist of one person strikes another in the teeth and a break in the skin occurs.[60] The most common cause is a fight, although cases can occur during contact sports. The metacarpophalangeal joint of the middle finger of the dominant hand is most often involved.[49] The break in the skin may be only 2 to 5 mm in length but often results in penetration into the joint or even into bone. Patients and physicians may underestimate the potentially serious nature of these wounds. Bacteria penetrate the knuckle area during the initial contact and, on relaxation of the hand, are carried by the tendons proximally into the potential spaces of the hand. Infection can spread laterally, between the collateral and accessory ligaments, or dorsally into the thin-walled bursa overlying the metacarpal head or into the palmar deep spaces of the hand. The swelling usually spreads proximally and not distally from the site of injury. Patients often avoid seeking attention initially because of the circumstances surrounding the injury and 6 to 8 hours later seek medical attention with a painful, throbbing, swollen, infected hand. Purulent exudate can be foul-smelling if *P. melaninogenica* or other anaerobes are present.

The range of motion of the hand usually is limited by swelling and edema but also can be limited as a result of tendon or nerve injury or severance. Osteomyelitis, which usually involves the small bones of the hand, often is manifested as continued pain, swelling, and erythema with or without drainage at 10 days to 3 weeks after the injury has occurred. Osteomyelitis and septic arthritis caused by *E. corrodens*, often in association with α-hemolytic streptococci, frequently are insidious and persistent and may lead to amputation, especially if treated with the wrong antibiotics.[49] Permanent limitation of range of motion and joint stiffness can occur. Other complications include fracture, collar-button abscess, and muscle atrophy.

Reports[5,70,106] have noted the transmission of HIV from biter to victim. HIV is isolated uncommonly from the saliva of infected persons, and when it has been recovered, it has been in low number. Consequently, the possibility of HIV transmission is considered unlikely, although it is not negligible. One report reviewed instances of HIV transmission by human bites and concluded that "no well documented case of HIV transmission through bites exists"; the risk of HIV transmission is possible biologically but appears to be unlikely.[98] A review and commentary of professional sports-related injuries also noted the unlikely possibility for HIV to be transmitted by sporting events and outlined similar commonsense control measures.

DIAGNOSIS AND TREATMENT

The most important aid in establishing the diagnosis of infection after bite wounds is the proper use of wound cultures. A culture specimen need not be obtained from children evaluated in the immediate postinjury period (the first 8 hours) unless the bite is located on the face or hand or signs of infection are present. Isolates from an uninfected but contaminated wound do not predict the future development of infection. Routine determination of the microorganisms colonizing bites on the face or hands is useful because of the potentially devastating consequences of infection at these locations. After the wound has been cleansed, culture should be performed routinely when evaluation is at an interval exceeding 8 hours from the time of injury, except for wounds evaluated more than 24 hours after injury with no signs of infection.

When material is obtained for wound culture, the microbiology laboratory should be informed that the source of the specimen is a bite wound. This information should optimize accuracy because *P. multocida* can be mistaken morphologically for *Neisseria* or *Haemophilus influenzae*. Appropriate media must be used for the isolation of anaerobes, and gram-negative rods should be considered pathogens. A blood culture should be performed if fever or systemic toxicity is evident, although associated bacteremia occurs rarely. Diagnostic imaging is indicated when the periosteum has been penetrated. Computed tomographic or magnetic resonance imaging can detect periosteal defects, particularly in children with cranial

bite wounds. For patients in whom wound infection has extended locally, sutures, if present, should be removed and material from the involved tissue compartment harvested for study. Material should be aspirated from areas of cellulitis or drained from areas of frank abscess formation. If osteomyelitis is suspected, a bone biopsy specimen should be submitted for Gram stain, culture, and histopathologic evaluation. If the course of the wound infection is indolent, acid-fast stains and mycobacterial cultures should be performed. Serum for serologic testing should be obtained from patients with symptoms suggesting a systemic infection. The details of the indicated diagnostic evaluation for systemic infections transmissible by animal and human bites are specified in the appropriate chapters.

The basic elements of management are outlined in Table 248-7. The wound should be cleansed with normal saline, and any foreign body or debris and necrotic tissue should be removed. Cautious débridement is indicated for some wounds, with care being taken to not create a potential skin defect. The wound then is irrigated, with a syringe and needle/catheter tip used as a high-pressure jet to diminish the bacterial inoculum. Puncture wounds should be cleansed but not irrigated because irrigation may damage tissues further.

The value and risks associated with primary closure in patients who are initially seen less than 8 hours after injury and without any symptoms or signs of established infection have not been studied in a prospective or randomized manner. Early primary closure has been successful for wounds to the face and neck.[117] The blood supply to the head and face area is superior to that of most other anatomic areas, and these areas are rarely dependent; therefore, edema and swelling resolve more rapidly or do not develop. In one prospective study, primary closure in patients presenting less than 8 hours after injury was associated with only slightly higher development of wound infection than that occurring after non–bite wound lacerations.[22] Most nonpuncture animal bite wounds except those involving the hands or feet can be treated by primary closure without substantially increasing the risk for development of infection.[43] Wounds to the hands should be observed and left open for either delayed primary or secondary closure. Infected wounds should not be closed.

Some clinicians prefer to approximate wound edges with adhesive strips or tissue adhesive rather than to suture wounds. In cases of clenched-fist injury, a hand surgeon should examine the patient to determine whether the joint capsule or bone has been compromised. With many hand infections, especially after exploration of clenched-fist injuries, immobilization in a plaster splint is recommended. Elevation of a swollen or inflamed part is crucial to healing. The elevation should be maintained above the level of the heart. Legs and hands also can be elevated with pillows.

Definitive data on which to base the use of antibiotic prophylaxis after animal bites are lacking. Smith and colleagues[107] summarized prospective clinical trials that have addressed the issue. Significantly lower infection rates were observed for prophylaxis of wounds in patients presenting at 9 to 24 hours after injury but not for those presenting less than 9 hours later in another study.[15] Prophylactic dicloxacillin, cephalexin, or erythromycin was not beneficial therapy for low-risk dog bite wounds in another prospective study because infection rates for wounds in both the antibiotic and control groups did not exceed 5 percent.[28] A meta-analysis of eight randomized trials totaling 783 patients with dog bite wounds found that prophylactic antibiotics did reduce the incidence of infection.[24] The estimated cumulative incidence of infection was 16 percent in controls, and the relative risk was 0.56 (95% CI, 0.38-0.82) in patients given antibiotics. Treatment of approximately 14 patients was required to prevent one infection. Some researchers consider antibiotic use therapeutic rather than prophylactic in this setting and suggest that antibiotic therapy be given in all cases of dog bites except those initially evaluated more than 24 hours after injury with no clinical signs of infection.[119]

Until additional data are available, a reasonable approach appears to be administration of prophylactic antibiotics in the following circumstances: dog bites more than 8 hours old; moderate to severe bites less than 8 hours old, especially if edema or crush injury is present; puncture wounds, particularly if bone or joint penetration may have occurred; facial wounds; all hand or foot bites; wounds in the genital area; and wounds in immunocompromised persons.[47,115]

Antimicrobial agents should be selected empirically according to the most likely pathogens and their usual

TABLE 248-7 Management Procedures for Bite Wounds

Obtain history from patient
Situation leading to injury
Place of occurrence
Patient allergies
Other medications (potential interactions)
Perform evaluation of patient
Nerve function
Tendon function
Vascular integrity
Range of motion
Potential bone and joint involvement
Diagram or photograph wound
Mark leading edge of cellulitis
Culture wound (if infected)
Irrigate wound (do not irrigate puncture wounds)
Débride wound cautiously
Obtain diagnostic imaging for penetrating injuries overlying bones or joints, if fracture suspected or foreign body suspected
Drain abscesses
Operative débridement (for removal of devitalized tissue and for severe bites, as indicated)
Administer antimicrobial agents (prophylactic therapy, 3 to 5 days; longer duration for established infection)
Elevate injured area
Close the wound (see text)
Immobilize wound area (3 days for hands)
Have the patient exercise the injured area (if previously immobilized)
Administer tetanus toxoid
Submit health department report (if required)

TABLE 248-8 **Comparative in Vitro Antimicrobial Activity of Selected Oral Antimicrobial Agents Against Common Bite Wound Pathogens**

	*Staphylococcus aureus**	*Eikenella corrodens*	Streptococci	*Haemophilus*	*Pasteurella*	Anaerobes

susceptibility patterns to antimicrobial agents.[50,57] If cultures are performed, therapy should be adjusted according to the organisms isolated and their specific susceptibility to antimicrobial agents. The activity of antibiotics commonly used against the usual bite wound pathogens is outlined in Table 248-8. Common pathogens to be considered in the selection of antimicrobial therapy include streptococci, *S. aureus*, *Haemophilus* spp., *E. corrodens*, *P. multocida*, and β-lactamase–producing oral anaerobes. The oral agent of choice is amoxicillin–clavulanic acid; for penicillin-allergic children, a combination such as an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin can be substituted.[3] Many other combination regimens, including cefuroxime plus clindamycin or metronidazole, may be used. The intravenous agents of choice are ampicillin-sulbactam and ticarcillin-clavulanate.[3] For penicillin-allergic children, combination therapy with an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin or meropenem should be administered.[3] Consideration should be given, in the era of methicillin-resistant *S. aureus*, to empirical addition of vancomycin to children with serious bite wounds, pending the results of cultures. Additional potentially useful intravenous agents include cefoxitin, meropenem or ertapenem, and combinations of such agents as cefuroxime or cefotaxime plus metronidazole.

First-generation cephalosporins are of limited utility because of poor activity against *E. corrodens* and some anaerobes[51] and should not be used as empirical monotherapy. Erythromycin also has poor activity against *P. multocida*, *E. corrodens*, and *Fusobacterium nucleatum*,[51] and its use as monotherapy can lead to therapeutic failure. Newer macrolides, including azithromycin, show improved activity compared with erythromycin against the spectrum of bite wound pathogens, but *Haemophilus* spp. and *F. nucleatum* remain relatively resistant.[57]

The quinolones, particularly moxifloxacin, exhibit broad activity against the pathogens implicated in bite wounds.[55,56,112] Linezolid, an oxazolidinone, appears to be more active than the macrolides against the gram-positive organisms and fusobacteria isolated from human bite wounds, but some aerobic gram-negative organisms are at the susceptibility breakpoint.[54] Once patient-specific cultures return, antimicrobial therapy should be adjusted in accordance with the patient's individual isolates and susceptibility pattern. The duration of antimicrobial therapy is determined by the type and severity of infection. Prophylactic antimicrobial agents typically are given for 3 to 5 days. If any question exists about the prompt filling of a prescription because of financial or other concerns, a dose of intramuscular or intravenous antibiotics should be administered and hospitalization considered.

Patients' wounds should be re-examined within 24 to 48 hours. If outpatient therapy is initiated and the cellulitis advances, hospitalization is indicated. Indications for hospitalization also include patient noncompliance and virtually all clenched-fist injuries.

As a general guideline, a suggested duration of therapy, assuming that proper drainage has been established, is 10 days for cellulitis or localized abscess, 2 to 3 weeks for tenosynovitis, and 3 to 6 weeks for osteomyelitis. When improvement is evident, treatment can be completed orally. At least 4 weeks of intravenous therapy should be administered to patients with endocarditis. Although the number of patients is too small for the required dosage to be established with certainty, ampicillin (400 mg/kg/day) has been used successfully for the treatment of *P. multocida* meningitis.[59]

In every child sustaining a bite wound, immunization status should be determined to assess the need for tetanus prophylaxis and whether rabies prophylaxis should be undertaken (see the appropriate chapters).

REPTILE BITES

Approximately 8000 people in the United States are bitten yearly by poisonous snakes. Approximately half occur in people younger than 20 years. The curiosity of children can contribute to this exposure because many are bitten while handling poisonous snakes.[91] Boys are more likely than girls to incur snake bites requiring antivenom therapy.[84] An average of five persons die of snake bites each year.[73]

Venomous snakes are divided into four families, two of which, the Crotalidae (rattlesnakes, copperheads, and water moccasins) and the Elapidae (coral snakes), are found in the United States. Snake venoms are among the most complex of proteins. The local effects of the venom of pit vipers (Crotalidae), which is rich in proteolytic activity, include swelling, pain, edema, ecchymosis, and tissue necrosis with the formation of bullae.[103] Systemic effects result from increased blood vessel permeability and hemolysis and may include hematuria, hematemesis, and disseminated intravascular coagulopathy. The venom of the eastern coral snake causes minimal local tissue destruction. It is a neurotoxin that produces paresthesia of the involved extremity, followed by involvement of the cranial nerves and bulbar paralysis.

Goldstein and associates[53] isolated 58 aerobic and 28 anaerobic organisms after culturing the venom from 15 rattlesnakes. The aerobes most commonly isolated were *Pseudomonas aeruginosa*, *Proteus* spp., and *Staphylococcus epidermidis*. Among the anaerobes, *Clostridium* spp. were the isolates found most frequently; *Bacteroides fragilis* also was recovered. Defecation of prey during ingestion contributes to this preponderance of gastrointestinal flora. When the fangs are cleansed carefully before collection, the venom itself is sterile, thus indicating that bacterial isolates potentially contaminating snake bite wounds are a reflection of the oral flora.

Alligators are generally not aggressive toward humans.[72] In persons sustaining alligator bite wounds, infection is caused most commonly by *Aeromonas hydrophila*. A report of mixed infection with *A. hydrophila*, *Enterobacter agglomerans*, and *Citrobacter diversus* and the frequency with which *Proteus vulgaris* and *Pseudomonas* spp. are isolated from alligator mouths suggest that treatment of alligator bites should be directed at gram-negative species.[36] *Vibrio* infection should be suspected in victims of shark bites as well as in all wounds exposed to salt water.[92] *Aeromonas* spp. and other gram-negative bacilli as well as *S. aureus* and anaerobes can infect shark bites.[100]

The exotic pet industry is growing in the United States, and the common green iguana is a popular pet. Few cases of infections from iguana bites have been reported and most bites do not have serious effects because these creatures are generally nonaggressive, but *Serratia marcescens* cellulitis has been observed.[61,38]

The inflammatory changes of envenomation can be difficult to differentiate from those of infection. At least one instance of osteomyelitis as a complication of an infected snake bite has been documented.[102] Some experts suggest use of a broad-spectrum antibiotic for injuries with severe tissue involvement but not for bites with minor or minimal envenomation.[102] Others suggest that prophylactic antibiotics are not required in snake bite victims.[78,114] Amoxicillin-clavulanate is an appropriate oral antimicrobial and ampicillin-sulbactam plus gentamicin is an appropriate parenteral regimen for empirical treatment of reptile bite wounds.[3] The oral alternatives for penicillin-allergic children are the same as those given for other animal bite wounds; one parenteral regimen for a penicillin-allergic child is clindamycin plus gentamicin. Treatment should be guided by the results of Gram stain and susceptibility testing.

PREVENTION

Bite wounds are, at least in part, preventable injuries. Prevention strategies include appropriate infection control measures in the sports setting and education of young athletes as well as their coaches and trainers. Bites can occur in the daycare setting, even when caregivers are vigilant. A cross-sectional survey of 5- to 15-year-olds found that dog bite prevention knowledge was poor, particularly among younger children.[29] There is as yet no direct evidence that educational programs actually lead to a reduction in dog bite rates in children and adolescents. Educating young children could improve their attitude and behavior toward dogs, and data are needed to evaluate dog bite rates as outcomes of such interventions.[31]

Acknowledgment

The author appreciates the contributions to prior editions by Dr. Ellie J. C. Goldstein in his chapter "Human Bites." Many parts of his excellent chapter have been retained unchanged in this revision.

CHAPTER 249

BIOTERRORISM

Robert J. Leggiadro

The intentional delivery of *Bacillus anthracis* spores through mailed letters or packages established the clinical reality of bioterrorism in the United States in the autumn of 2001.[8,43] An understanding of the epidemiology, clinical manifestations, and management of the more credible biologic agents is critical to limiting morbidity and mortality from a bioterrorism attack.[15,30,38,49]

Implementation of an effective response to deliberate release of biologic agents by terrorists requires detection and reporting of cases as soon as possible.[6,12] Prompt recognition of unusual clinical syndromes and increases above seasonal levels in the incidence of common syndromes or deaths from infectious agents is critical to an effective response.[6,22,38,47]

HISTORY

The concept of biologic warfare or terrorism is not a new one. In 1346, the Tatar force attacking Kaffa (also Caffa, now Feodossia, Ukraine) was struck by a plague epidemic.[13,66] To take advantage of this development, the Tatars catapulted the corpses of their plague victims into Kaffa. An outbreak of plague did occur in the city, representing one of the first biologic attacks recorded.[13,66]

Smallpox first was used as a biologic weapon during the French and Indian War of 1754 to 1767.[13] Apparently, British troops deliberately infected Native Americans with smallpox by giving them blankets from infected patients.

A secret branch of the Japanese army, Unit 731, reportedly caused outbreaks of plague by dropping plague-infected fleas over populated areas of China in World War II.[37] Bomb experiments of weaponized anthrax spores were conducted by the Allies on uninhabited Gruinard Island near the coast of Scotland and resulted in heavy contamination in 1942.[57] Viable anthrax spores persisted until the island was decontaminated with formaldehyde and seawater in 1986.

In response to a perceived German biologic warfare threat, the United States began research into the offensive use of biologic agents in 1943 at Camp Detrick (renamed Fort Detrick in 1956) in Frederick, Maryland.[13] President Nixon stopped all offensive biologic and toxin weapon research and production by executive order in 1969. Included among the agents destroyed as a result of this action were *B. anthracis*, botulinum toxin, *Francisella tularensis*, *Coxiella burnetii*, Venezuelan equine encephalitis virus, *Brucella suis*, and staphylococcal enterotoxin B. Begun in 1953, the U.S. defensive program at Fort Detrick continues today as the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID).[13]

The Biological and Toxin Weapons Convention was ratified in 1972 and went into effect in 1975.[67] It prohibits the development, production, stockpiling, or transfer of biologic weapons agents (microbial pathogens and toxins)

for other than peaceful purposes and any devices used to deliver these agents. One hundred forty-three states are parties to the convention, with an additional 18 signatories. Unfortunately, the treaty was not accompanied by effective provisions for verification.

Although the Soviet Union signed the convention at its inception in 1972, it formed and funded an organization known most recently as Biopreparat (Chief Directorate for Biological Preparations) 2 years later.[18] This organization was designed to carry out offensive biologic weapons research, development, and production concealed behind legal and civil biotechnology research. Its capacity for production of biologic weapons included plague, tularemia, glanders, brucellosis, anthrax, smallpox, and Venezuelan equine encephalomyelitis.[1]

An incident at a military microbiology facility in Sverdlovsk (now Yekaterinburg) in the former Soviet Union in 1979 proved to be a grim warning of the dangers of biologic weapons science.[51] An accidental aerosolized release of anthrax spores resulted in at least 79 cases of anthrax, including 68 deaths. This largest reported outbreak of inhalational anthrax occurred in people living or working within a 4-km zone downwind of the facility.

Iraq's biologic warfare program commenced in earnest in 1985 after initial explorations in the late 1970s.[69] By the end of the Persian Gulf War in 1991, Iraqi scientists had investigated the biologic warfare potential of five bacterial strains, one fungal strain, five viruses, and four toxins. The United Nations Special Commission suspects that from 1991 to 1995, Iraq actively preserved biologic weapons capability, including botulinum toxin, anthrax, and *Clostridium perfringens* spores.[18]

The Japanese cult Aum Shinrikyo made several unsuccessful attempts at disseminating anthrax from rooftops and trucks in central Tokyo in the early 1990s before successfully releasing sarin nerve gas into Tokyo's subways and killing a dozen people in 1995.[68] A large community outbreak of salmonellosis was caused by the intentional contamination of restaurant salad bars for political reasons by members of a religious commune in The Dalles, Oregon, in 1984.[61]

EPIDEMIOLOGY

Potential biologic weapons share several characteristics. Ease of acquisition and production is a primary consideration. Other ideal properties include the potential to be aerosolized (particle size, 1-10 μm) and dispersed over a wide geographic area as well as resistance to sunlight, desiccation, and heat. The potential to cause lethal or debilitating disease and person-to-person transmission are important features, as is lack of effective therapy or prophylaxis.[23,30,37]

Any small or large outbreak of disease merits evaluation as a potential biologic event.[55] Unusually high rates of disease (e.g., a cluster of life-threatening pneumonia cases in previously healthy adults) as well as unusual clinical syndromes should signal a warning. Once definition of the cause and rate of attack have been determined, an epidemic curve based on the number of cases during a specific time can be calculated. The epidemic curve in a biologic event triggered by a point-source exposure most likely would be compressed, with a peak occurring in a matter of hours or days. The occurrence of a second curve peak would be possible with contagious agents as a result of person-to-person transmission. The steep epidemic curve expected in a bioterrorism attack is similar to what would be seen with other point-source exposures, such as food-borne outbreaks.

Several epidemiologic clues may be helpful in determining whether further investigation into an outbreak as a potential biologic attack is warranted. Major indicators are a large epidemic, especially in a discrete population; more severe disease than expected for a given pathogen; and a disease unusual for a given geographic area (e.g., pulmonic tularemia in an urban setting). Multiple simultaneous epidemics of different diseases, outbreaks with both human and zoonotic consequences, and unusual strains or susceptibility profiles are additional helpful parameters. Variable attack rates as a function of agent release relative to the interior or exterior of a building also would be useful.[55] Although most bioterrorism attacks will be covert,[6,12] intelligence revealing plans for an attack, terrorist claims of deliberate release, or direct physical evidence of an attack obviously would point to a biologic event.

The emergence of mosquito-borne West Nile virus encephalitis in New York City in the summer of 1999 is an example of a naturally occurring outbreak that had elements of a potential bioterrorist attack.[6,22,59] This outbreak represented a disease occurring in an unusual (previously nonendemic) area as well as one with zoonotic (birds) in addition to human consequences. It marked the first documented appearance of West Nile virus in the Western Hemisphere and the first arboviral outbreak in New York City since the yellow fever epidemics of the 19th century.[22] A large avian die-off, affecting primarily crows, preceded the outbreak in humans by at least several weeks.

CRITICAL BIOLOGIC AGENTS

In addition to anthrax, critical biologic agents include brucellosis, plague, Q fever, and tularemia; smallpox, viral encephalitis, and viral hemorrhagic fever; and illnesses related to botulinum and staphylococcal enterotoxin B toxins (Table 249-1).[6,44,47] The five more credible biologic agents are discussed further.

Anthrax

Bacillus anthracis is a large sporulatory, gram-positive rod with three distinct life cycles featuring multiplication of spores in soil, animal (herbivore) infection, and human infection.[45] Anthrax continues to occur in developing countries where the organism is highly endemic and the use of animal anthrax vaccine is not comprehensive (e.g., Iran, Iraq, Turkey, Pakistan, and sub-Saharan Africa). Human cases may be classified as either agricultural or industrial. Herders, butchers, and slaughterhouse workers in direct contact with infected animals are susceptible to acquiring agricultural infection, and workers in mills that

process animal hair and those handling bone meal may acquire industrial infection.[56]

The three forms of human anthrax are cutaneous, inhalational, and gastrointestinal. The most common form is cutaneous, which is acquired through contact with an infected animal or animal products. The much less common inhalational form results from the deposition of spores in the lungs, and gastrointestinal anthrax occurs after the ingestion of infected meat. Because human-to-human transmission of anthrax has not been reported, standard precautions are recommended for hospitalized patients with all forms of anthrax infection.[39,60]

In the United States, 224 cases of cutaneous anthrax were reported between 1944 and 1994.[39] Most cases in recent decades were a result of exposure to wool or animal hair.[56] Cases of cutaneous, inhalational, and gastrointestinal anthrax have been reported in persons who made or handled imported animal-hide drums or participated in drumming events where imported animal-hide drums contaminated with *B. anthracis* spores were used.[17,25,40]

The clinical features and course of the first 10 confirmed cases of inhalational anthrax associated with bioterrorism in the United States in the fall of 2001 have been reported.[43] Epidemiologic investigation indicated that the outbreak was a result of intentional delivery of *B. anthracis* spores through mailed letters or packages. The median incubation period was 4 days and ranged from 4 to 6 days. Several clinical features of these patients were not emphasized in earlier reports of inhalational anthrax, a previously rare disease. Drenching sweating, nausea, and vomiting were common manifestations of the initial phase of illness in this outbreak. Pleural effusions were a remarkably consistent clinical feature. No predominant underlying diseases or conditions were noted.

None of the 10 patients had an initially normal chest radiograph. In addition to characteristic mediastinal widening (Fig. 249-1), paratracheal or hilar fullness, pleural effusions, and parenchymal infiltrates were noted. Computed tomography of the chest was more sensitive than chest radiography in revealing mediastinal lymphadenopathy, and an elevation in the proportion of neutrophils or band forms represented an early diagnostic clue.

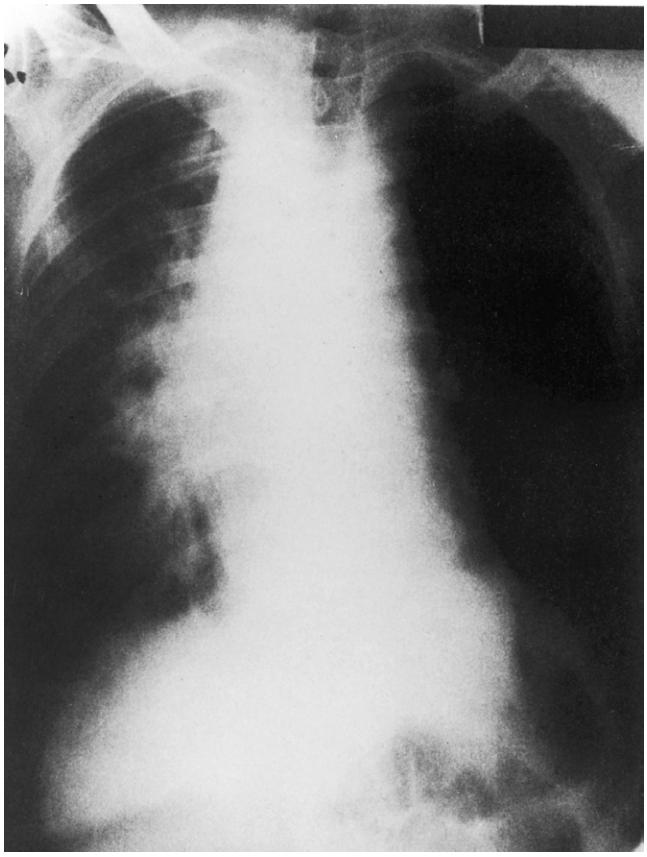

FIGURE 249-1 ■ Chest radiograph showing a widened mediastinum secondary to hemorrhagic mediastinitis in a patient with a fatal case of inhalational anthrax. (From LaForce FM, Bumford FH, Feeley JC, et al. Epidemiologic study of a fatal case of inhalation anthrax. *Arch Environ Health* 1969;**18**:798-805. Reprinted with permission of Helen Dwight Reid Educational Foundation. Published by Heldref Publications, 1319 Eighteenth St., NW, Washington, DC 20036-1802. Copyright 2000.)

Inhalational anthrax previously was reported to be a biphasic illness with influenza-like symptoms such as fever, cough, malaise, fatigue, and chest discomfort in the first phase, followed briefly by 1 to 2 days of improvement before development of the acute phase 2 to 5 days later.[14] However, this brief period of improvement between the initial and fulminant phases of illness was not observed in the first intentional outbreak associated with mail.[36]

The 55 percent survival rate in these patients was higher than previously reported (<15%). Limited data on treatment of survivors suggest that early treatment with a fluoroquinolone and at least one other active drug (e.g., rifampin, clindamycin, or vancomycin) may improve survival.[8,60] A systematic review of 82 cases of inhalational anthrax from 1900 to 2005 revealed several findings. Initiation of antibiotic or anthrax antiserum therapy during the prodromal phase of disease was associated with a substantial improvement in short-term survival. In addition, both multidrug antibiotic regimens and pleural fluid drainage were associated with decreased mortality.[31]

Nasal congestion, rhinorrhea, and sore throat, infrequently seen in this series, might help distinguish

influenza-like illness from inhalational anthrax.[16] Newer diagnostic methods for *B. anthracis* infection include polymerase chain reaction assay, immunohistochemistry, and sensitive serologic tests. Recommendations for antibiotic treatment of inhalational anthrax include use of either ciprofloxacin or doxycycline plus one or two additional antibiotics known to be active in vitro against *B. anthracis*. Additional antibiotics include clindamycin, vancomycin, imipenem, meropenem, chloramphenicol, penicillin, ampicillin, rifampin, and clarithromycin. Corticosteroids should be considered for meningitis or significant mediastinal edema.[3,36] Passive immunization with a polyclonal or monoclonal antibody product may offer adjunctive value to antibiotic therapy, especially if the organisms are resistant to multiple antibiotics.[26] Raxibacumab is a human IgG1 monoclonal antibody directed against protective antigen, a component of anthrax toxin. A single dose of raxibacumab improved survival in rabbits and monkeys with symptomatic inhalational anthrax.[52]

Cutaneous anthrax is characterized by a skin lesion evolving from a papule, through a vesicular stage, to a depressed black eschar, often surrounded by significant edema and erythema.[20,58,60] The lesion, which may mimic a spider bite, is usually painless and located on exposed parts of the body (i.e., face, neck, and arms). The incubation period ranges from 1 to 12 days but commonly is less than 7 days. With effective antimicrobial therapy, fatalities are rare occurrences (<1%). Cutaneous anthrax occurred in a 7-month-old infant who was exposed at his mother's workplace as a result of the fall 2001 attack. This infant displayed severe microangiopathic hemolytic anemia with renal involvement, coagulopathy, and hyponatremia, unusual findings with cutaneous anthrax.[24]

The organism grows readily on sheep blood agar and forms rough, gray-white colonies 4 to 5 mm in size with characteristic comma-shaped or "comet tail" protrusions.[45] *B. anthracis* is differentiated from other *Bacillus* spp. by an absence of the following: hemolysis, motility, growth on phenylethyl alcohol blood agar, gelatin hydrolysis, and salicin fermentation. Biosafety level 2 conditions for safe specimen processing in the microbiology laboratory and prompt confirmation of suspected isolates at the Centers for Disease Control and Prevention (CDC) or the USAMRIID in Fort Detrick are warranted.[39,56]

Postexposure vaccination with an inactivated, cell-free anthrax vaccine is indicated along with ciprofloxacin, doxycycline, or amoxicillin chemoprophylaxis after a proven biologic event has occurred.[60,64] Recommendations for postexposure prophylaxis (and prolonged therapy after initial therapy for inhalational or cutaneous anthrax) include a 60-day course of antibiotics followed by careful clinical observation. Preexposure vaccination may be indicated for the military and other select populations or for groups for which a calculable risk can be assessed.[64]

Smallpox

After a worldwide eradication program, the last known endemic case of smallpox occurred in Somalia in 1977, and the World Health Organization declared smallpox eradicated in 1980.[28] No animal reservoir exists. Current recognized stocks of variola virus are authorized only at the CDC in Atlanta and a Russian state laboratory in Koltsovo. However, additional variola isolates, either long held unreported or acquired through security breaches, also may exist. The World Health Assembly agreed to postpone setting a date for destruction of the world's remaining smallpox virus stocks until 2014, when the 67th annual World Health Assembly will once again take up the question of a destruction date.[32] The decision on a time line for destruction has been postponed four other times so that crucial research may be completed. Routine vaccination against smallpox ceased in the United States in 1972 and for military personnel in 1990. In December 2002, in response to the possible threat of an intentional release of smallpox virus, the U.S. government implemented a program to immunize select military and public health personnel against smallpox.[65] Release of an aerosol would be the most likely route of transmission during an act of bioterrorism.

Smallpox is transmitted by respiratory secretions and requires close person-to-person contact. The incubation period generally is 12 to 14 days, with a range of 7 to 17 days. The prodromal illness of classic variola major features an acute onset of malaise, fever, rigors, vomiting, headache, and backache. Two to 3 days later, a discrete rash appears on the face, hands, forearms, and mucous membranes; it spreads to the legs and then centrally to the trunk during the second week of illness. Lesions progress from macules to papules to pustular vesicles during the course of 1 to 2 days. Umbilicate scabs form 8 to 14 days after onset and leave depressions and depigmented scars.[29]

In contrast to varicella (chickenpox), the rash of smallpox is centrifugal, with a concentration of lesions on the face and extremities, including the palms and soles, versus the trunk in varicella (Fig. 249-2). Smallpox lesions also are synchronous in stage of development, whereas the lesions of chickenpox appear in crops every few days, which results in lesions at very different stages of maturation in different areas of the skin. Any confirmed case of smallpox represents an international emergency and must be reported to national authorities through local and state health departments.[28]

Historically, the mortality rate associated with smallpox was 30 percent for unvaccinated contacts, and currently no antiviral therapy of proven efficacy has been developed. Supplies of vaccinia vaccine and vaccinia immune globulin intravenous (VIGIV) are available only through the CDC.[28] Postexposure vaccination and strict quarantine are indicated for all household and other face-to-face contacts of suspected smallpox cases.[28]

In a limited outbreak with few cases, hospitalized patients should receive care in negative-pressure rooms with high-efficiency particulate air filtration. In addition, precautions using gloves, gowns, and masks are indicated. Home isolation and care are appropriate for most patients in larger outbreaks.[28]

Between January 24 and October 31, 2003, 37,901 volunteers in 55 jurisdictions received 38,885 smallpox vaccinations through the U.S. Department of Health and Human Services program, with a take rate of 92 percent.[11]

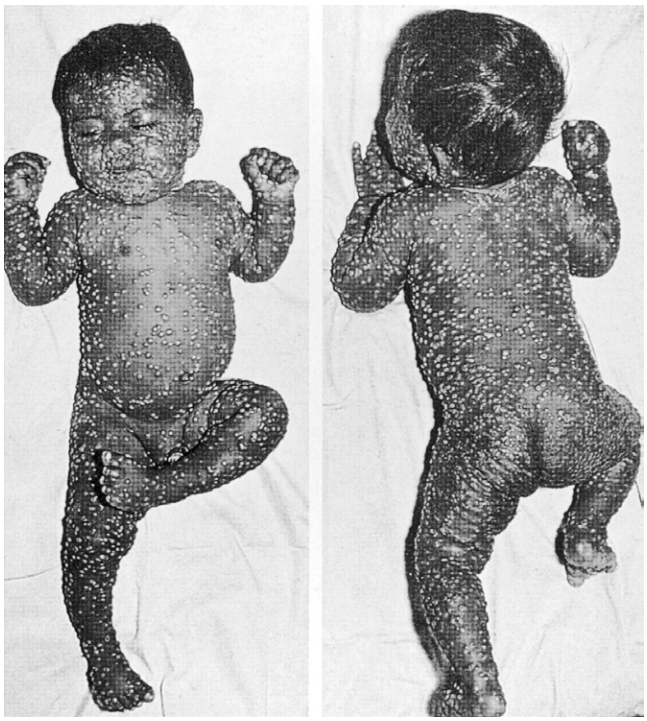

FIGURE 249-2 ■ The lesions of smallpox are at the same stage of development on each area of the body, are deeply embedded in the skin, and are more densely concentrated on the face and extremities. (From Henderson DA. Smallpox: clinical and epidemiologic features. *Emerg Infect Dis* 1999;**5**:537-9.)

The Vaccine Adverse Event Reporting System (VAERS) received 822 adverse event reports related to these vaccines, an overall reporting rate of 217 per 10,000 vaccinees; 722 nonserious reports to VAERS included multiple signs and symptoms of mild systemic and self-limited local reactions, including fever, rash, pain, and headache.[11]

No cases of preventable life-threatening adverse reactions, such as eczema vaccinatum, progressive vaccinia, or fetal vaccinia, were reported. No cases of vaccinia contact transmission occurred. No vaccinee or contact of this program received VIGIV. Rigorous smallpox vaccine safety screening, educational programs, and older vaccinees may have contributed to low rates of preventable life-threatening adverse reactions.[11]

Of the adverse events, 100 were designated serious, resulting in 85 hospitalizations, 2 permanent disabilities, 10 life-threatening illnesses, and 3 deaths. Among the serious adverse events, 21 cases were classified as myocarditis or pericarditis and 10 as ischemic cardiac events that were not anticipated on historical data. Two cases of generalized vaccinia and one case of postvaccinial encephalitis also were detected.[11]

The first confirmed case of eczema vaccinatum in the United States related to smallpox vaccination since routine vaccination was discontinued in 1972 was reported in 2007.[65] A 28-month-old child with refractory atopic dermatitis developed eczema vaccinatum after exposure to his father, a member of the U.S. military who had recently received smallpox vaccine. The child's mother also developed vaccinia infection.[65]

Treatment of the child included VIGIV, used for the first time in a pediatric patient; cidofovir, never previously used for human vaccinia infection; and ST-246, an investigational agent being studied for the treatment of orthopoxvirus infection.[65]

The child recovered without apparent sequelae or significant scarring. Although it is difficult to assess and differentiate the effects of specific therapeutic interventions, the child's immune system almost certainly played a role in the eventual control of the infection. This case illustrates the need for meticulous prevaccination screening and the potential hazards of widespread vaccination.[65]

ACAM2000, a second-generation smallpox vaccine produced in cell culture from a clonally purified master seed stock of vaccinia derived from the New York City Board of Health strain of vaccinia, has replaced the original Dryvax vaccine in the Strategic National Stockpile.[27] Replication-deficient smallpox vaccines, such as the modified vaccinia Ankara (MVA), and antivirals may offer a safer, more inclusive method of addressing smallpox vaccine–associated adverse reactions, including in individuals at risk for complications.[27]

Plague

Plague, a zoonotic illness caused by the gram-negative bacillus *Yersinia pestis*, is primarily a disease of rodents, with transmission occurring through infected fleas. Human disease is acquired through rodent flea vectors as well as respiratory droplets from animals to humans and humans to humans. Transmission of plague to humans in the United States primarily is by the bites of fleas from infected rodents. During 1990-2005, a total of 107 cases of plague were reported in the United States, a median of 7 cases per year, most commonly in the southwestern United States.[34] Indications of a deliberate release of plague bacilli would include the occurrence of cases in locations not known to have enzootic infection, in persons without known risk factors, and in the absence of previous rodent deaths.[37] Travelers can acquire plague in one area and become ill in another area where plague is not endemic (i.e., peripatetic plague).[35]

The three clinical forms of human plague are bubonic, primary septicemic, and pneumonic. Bubonic plague, characterized by the development of an acute regional lymphadenopathy, is the most frequent clinical form and accounts for 76 percent of U.S. cases.[34] However, the pneumonic form would be the most likely manifestation as a result of release of an aerosol during a biologic attack.[23,37] This clinical form is the least common, but it has the highest mortality rate; it is almost always fatal if antibiotics are not begun within 24 hours of the onset of symptoms. Septicemic plague without obvious lymphadenopathy may be more difficult to diagnose than is bubonic plague because of nonspecific manifestations (i.e., fever, chills, abdominal pain, nausea, vomiting, diarrhea, tachycardia, tachypnea, and hypotension).[37] Delay in establishing the diagnosis and initiating appropriate therapy may lead to death.[34,37,48]

The incubation period for primary pneumonic plague is 1 to 3 days. Fever, chills, headache, and rapidly progressive weakness are characteristic of all clinical forms of plague. Cough, dyspnea, and hemoptysis are distinctive of primary pneumonic plague. The sudden appearance of a large number of previously healthy patients with fever, cough, shortness of breath, chest pain, and a fulminant course leading to death should suggest the possibility of pneumonic plague or inhalational anthrax immediately. The presence of hemoptysis would strongly suggest plague.[4,37]

Y. pestis may be identified in clinical specimens by Gram, Wright-Giemsa, Wayson, and immunofluorescence staining methods in addition to standard bacterial culture. Appropriate clinical specimens include lymph node aspirates and blood as well as tracheal washes or sputum smears if pneumonic plague is suspected. Tests used to confirm a suspected diagnosis include antigen detection, immunoglobulin M (IgM) enzyme immunoassay, and polymerase chain reaction assay.[9,37] When plague is suspected, both the state and public health laboratory and public health authorities should be notified promptly.[63]

Effective therapy is available in the form of streptomycin, gentamicin, chloramphenicol, doxycycline, and ciprofloxacin.[37] Parenteral aminoglycoside therapy is recommended in a contained casualty setting (modest number of patients requiring treatment); oral therapy is recommended in a mass casualty scenario.[37] The potential benefits of doxycycline and ciprofloxacin in the treatment of pneumonic plague infection in children substantially outweigh the risks.[12,37] An inactivated, whole-cell *Y. pestis* vaccine was discontinued by its manufacturers in 1999 and no longer is available.[37]

In addition to standard precautions, droplet precautions are indicated for all patients with suspected plague until pneumonia is excluded and appropriate therapy has been initiated. Droplet precautions should be continued in patients with confirmed pneumonic plague for 48 hours after the initiation of appropriate therapy.[37] Only standard precautions are recommended for bubonic plague.

Tularemia

The etiologic agent of this zoonotic illness is *Francisella tularensis*, a gram-negative coccobacillus. The disease may be acquired from ticks and deer flies, contact with animals such as rabbits and rodents, ingestion of contaminated water, or inhalation of aerosols.[62] In a bioterrorist event, inhalation of an aerosol would be the most likely route of infection.[4,19] Human-to-human transmission of tularemia has never been reported. The annual incidence of tularemia in the United States is fewer than 200 cases; approximately 40% of all tularemia cases reported to the CDC each year occur in Arkansas, Oklahoma, and Missouri. All suspected or confirmed cases must be reported to health authorities.[62]

Clinical forms of the disease include ulceroglandular, glandular, oculoglandular, oropharyngeal, pneumonic, and typhoidal, the type reflecting the organism's portal of entry.[21,42] Either pneumonic alone or typhoidal, with or without a pneumonic component, would be the most likely clinical manifestation of tularemia as a result of aerosol release during a biologic attack.[4,19,62] A novel intraerythrocytic phase during *F. tularensis* infection was shown in a murine model of pulmonary tularemia.[33] The incubation period for tularemia is 3 to 6 days, with a range of 1 to 21 days. Typhoidal tularemia may be manifested as fever of unknown origin. Standard precautions are indicated for hospitalized patients with all forms of tularemia.[19]

The diagnosis is established most often by serologic testing, and isolation of *F. tularensis* from clinical specimens requires cysteine-enriched media or inoculation of laboratory mice. In addition to a need for special media, the laboratory should always be informed when tularemia is suspected because of the potential hazard to laboratory personnel. Suspected isolates should be confirmed by the CDC or USAMRIID through local or state health departments.[19]

Effective therapeutic agents include streptomycin, gentamicin, tetracycline, ciprofloxacin, and chloramphenicol; postexposure prophylaxis with doxycycline or ciprofloxacin may be considered.[19] The benefits of tetracycline or ciprofloxacin therapy outweigh the risks for children younger than 8 years in select clinical situations, including tularemia.[19,46] A live attenuated vaccine for preexposure use is not generally available in the United States.

Botulism

Seven distinct but related neurotoxins, A through G, are produced by different strains of *Clostridium botulinum*, an anaerobic gram-positive rod. The most common types in U.S. food-borne outbreaks are A, B, and E; outbreaks with unusual botulinum toxin types (i.e., C, D, F, and G or E not acquired from an aquatic food) would suggest deliberate release.[2] Classic neuroparalytic disease is acquired through the ingestion of preformed neurotoxin. Other forms include localized infection (wound botulism) and *C. botulinum* intestinal colonization in infants with in vivo toxin production (infant botulism). Botulism in the United States is seen most often in small clusters or single cases associated with home-canned foods. Although airborne transmission of botulinum neurotoxin does not occur naturally, aerosolization of preformed toxin would be the most likely route of transmission in a bioterrorism event.[2,23] Sabotage of food supplies is also possible. Botulism is not transmitted from human to human; standard precautions are recommended for hospitalized patients.

The incubation period for food-borne botulism generally is 12 to 36 hours (range, 6 hours to 8 days). The clinical manifestations of disease acquired by inhalation would be the same as those for food-borne botulism. Early manifestations include blurred vision, diplopia, and dry mouth. Patients are afebrile with a clear sensorium.

Later clinical features indicative of more severe disease include dysphonia, dysarthria, dysphagia, ptosis, and a symmetric, descending, progressive muscular weakness with respiratory failure.[2] Clinical suspicion is critical

because a recognized source of exposure may be absent in a biologic attack. Botulism is a reportable disease.

A toxin neutralization bioassay in mice is used to identify botulinum toxin in serum, stool, or food. *C. botulinum* also may be cultured from stool and food. Electromyography can be helpful diagnostically. Heptavalent (A-G) botulinum antitoxin (HBAT) of equine origin, available through a CDC-sponsored Food and Drug Administration Investigational Drug protocol, should be administered as soon as possible to patients symptomatic with botulism.[2,41] A pentavalent toxoid (PBT) of *C. botulinum* toxin types A, B, C, D, and E is no longer available for use as a vaccine.[53]

Viral Hemorrhagic Fever

The term *viral hemorrhagic fever* (VHF) refers to a clinical illness associated with fever and a bleeding diathesis caused by a virus belonging to one of four distinct families: Filoviridae (e.g., Ebola, Marburg), Arenaviridae (e.g., Lassa fever), Bunyaviridae (e.g., Rift Valley fever), and Flaviviridae (e.g., yellow fever). VHF agents are RNA viruses normally transmitted to humans from animal reservoirs or arthropod vectors, although the natural reservoirs and vectors of the Ebola and Marburg agents are unknown. Geographic distribution of these agents is as follows: Ebola and Marburg, Africa; Lassa, West Africa; New World arenaviruses, the Americas; Rift Valley fever, Africa and the Middle East; and yellow fever, Africa and the Americas. Most of these agents are considered serious, potential biologic threats because of their potential to be aerosolized and their high morbidity and mortality rates. Clinical features vary with the specific virus, but all are capable of causing fever, myalgia, prostration, petechiae, hemorrhage, and shock.[7]

Treatment generally is supportive, although ribavirin has some in vitro and in vivo activity against arenaviruses and bunyaviruses but not against filoviruses or flaviviruses. VHF-specific barrier precautions as well as airborne precautions are recommended for any patient with suspected or documented VHF. Effective prophylaxis after exposure to a VHF agent is not available, although guidelines for the use of oral ribavirin as postexposure prophylaxis for Lassa fever have been proposed on the basis of an extensive review of the literature and experience in the field.[5,7]

PREPAREDNESS AND RESPONSE

Being prepared for a bioterrorist attack or any other large-scale infectious disease outbreak relies on similar critical elements.[22,38,50,54,59] Clinician awareness and education are paramount. Because practicing physicians most likely will be the first group to encounter diseases caused by biologic weapons, they must be familiar with the signs and symptoms of the more credible biologic agents (e.g., smallpox, anthrax).[38,50,54] Recognition of an unusual case or cluster of illnesses should prompt a report to the local public health authorities.[10,22] Improved communication between human and animal health authorities is warranted because many potential bioterrorist agents, such as anthrax, brucellosis, Q fever, plague, and tularemia, are zoonotic diseases.[22] Knowledge of the processes by which the hospital laboratory, the local or state health department, or the CDC performs diagnostic studies to implicate or to exclude biologic agents also is important.[6,22,38] Local, state, and federal public health agencies must coordinate plans for dealing with a large-scale outbreak caused by a biologic event.[6,10,22,59] They should address rapid investigation of the outbreak, public education, mass distribution of antibiotics and vaccines, the capacity to care for mass casualties, and proper, expeditious treatment of the dead.[6,22,38,59]

APPROACH TO THE LABORATORY DIAGNOSIS OF INFECTIOUS DISEASES

This page intentionally left blank

CHAPTER 250

Bacterial Laboratory Diagnosis

Paula A. Revell • Lakshmi Chandramohan

Laboratory tests can lead to or confirm diagnoses as well as aid in choosing appropriate therapy. The challenge of the clinical diagnostic laboratory is to provide clinically relevant information in a timely manner by reporting accurate and significant results. However, laboratory diagnosis of bacterial infections begins at the bedside, not in the laboratory, with the appropriate collection and transport of specimens. This initial step is one of the most critical steps in the process of making an accurate laboratory diagnosis as no level of technical expertise or amount of specialized technology can correct for an improperly collected or transported specimen. Most bacteriology testing depends on the cultivation and identification of living organisms, and as such, more than any other area of the clinical laboratory, microbiology is affected by inappropriate specimen management practices. Examples of common problems include incorrect or insufficient specimen labeling, insufficient volume of specimen collected, incorrect transport media, and delays in transport of the specimen to the laboratory. Some common principles for quality specimen collection and transport are listed in Table 250-1.

In addition to culture-based methods of bacterial identification, non–culture-based techniques for several bacterial pathogens are described in this chapter.

CULTURE-BASED DETECTION

Whereas technologic advancements have been made in the area of direct pathogen identification by use of molecular methods as well as mass spectrometry, the isolation of live organisms is still critical, in particular because of the need to determine antimicrobial susceptibility results. Bacterial culture depends on the growth of organisms on various different types of culture media, including selective, differential, and enriched. Enriched media will support growth of the majority of bacterial strains, including fastidious organisms; examples include sheep blood agar and chocolate agar. Selective media inhibit the growth of certain bacteria while allowing the growth of others. The most common method of selecting against certain organisms is with the addition of antibiotics to the media; an example of this type of medium is oxacillin agar to select for methicillin-resistant *Staphylococcus aureus*. Differential media aid in distinguishing similar types of organisms on the basis of their phenotype when they are grown on the media. Examples of differential media include chromogenic agars that change color when a certain organism grows on the media and MacConkey agar, which permits the distinction between lactose-fermenting and non–lactose-fermenting gram-negative bacilli.

Each particular type of specimen has distinct requirements for optimal collection and transport as well as recommended media types to support growth of suspected organisms. The individual specimen-specific strategies for identification and diagnosis of various bacterial infections are described in the following sections.

Specimen-Specific Collection and Cultivation Requirements

Bloodstream Infection

Sepsis has long been associated with significant morbidity and mortality; according to the Centers for Disease Control and Prevention (CDC) National Center for Health Statistics, sepsis was the eleventh leading cause of death in the United States in 2009.[25] Given the significant impact of sepsis, the detection of microorganisms circulating in the bloodstream of a patient is among the most critical roles of the clinical microbiology laboratory. Detection of bacterial pathogens is typically accomplished through the incubation of a blood sample in a bottle that contains a specialized liquid medium on a continuously monitored blood culture system. A positive blood culture can confirm a cause of the septic event as well as allow appropriate antimicrobial susceptibility testing and thus optimal antibiotic therapy. The automated blood culture systems routinely used in microbiology laboratories are described as continuously monitored because the system takes a reading every 10 to 20 minutes to evaluate possible growth of microorganisms. Several systems are currently available with differences in detection methods, but all perform comparably. This constant monitoring is accomplished without entering the bottle, and thus the contamination rate for these systems is lower than that of the lysis-centrifugation system (Isolator, Wampole Laboratories, Cranbury, NJ).

The single variable with the greatest impact on the sensitivity of detection of bacterial pathogens in blood is the volume of blood that is cultured.[19,46] Whereas this observation is based primarily on data from studies of adult patients, several studies show that increasing the volume of blood cultured increases the sensitivity of detection in a pediatric population as well.[20] In addition, multiple studies have demonstrated that low-level bacteremia in pediatric patients is common, and thus by increasing the volume of blood cultured, the likelihood

TABLE 250-1 Principles for Quality Specimen Collection and Transport

Use sterile technique to minimize contamination.
Collect as close to the site of infection as possible.
Collect at optimal times to recover the pathogens of interest.
Obtain a sufficient quantity of the specimen to perform the requested tests.
Use appropriate collection devices and specimen containers to ensure recovery of all organisms.
Collect all microbiology specimens before the institution of antibiotics.
Properly label and seal the specimen container before transport.
Minimize transport time or maximize transport media. There is always some loss of viability during transport.

of detecting low-level bacteremia increases.[41] Because pediatric patients have a wide range of blood volumes, there is not one recommended volume for optimal blood culture collection. The most common approach to guiding appropriate volume of blood cultured from pediatric patients is the implementation of a weight-based guideline.[32]

As is the case with any specimen, blood cultures should be transported to the laboratory in a timely manner. Several studies have shown that delays in entry of blood culture bottles to the blood culture system can result in falsely negative cultures (decreasing sensitivity of detection) and increases in time to detection (delaying the reporting of positive results).[67] Optimally, the blood culture bottle should be loaded onto the blood culture system within 4 hours of collection. If delay in entry to the blood culture system is required, during the delay time, the sample should not be incubated at 37° C (98.6° F) as preincubation may significantly compromise results.[79] Optimal temperature for transport of blood culture bottles is room temperature.

Before the introduction of automated, continuously monitored blood culture detection systems, the detection of certain fastidious organisms required incubation times up to 2 weeks. However, with use of the automated systems, both routine and fastidious organisms will be detected within a 5-day incubation time. This 5-day incubation time is adequate for detection of fastidious organisms such as *Brucella*, *Francisella*, *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*, *Abiotrophia*, and *Granulicatella*.[18,80] Importantly, there are limitations to the routine blood culture; for example, *Streptobacillus moniliformis* is sensitive to even low levels of the anticoagulant SPS, which is added to aerobic blood culture bottles. In cases with suspected rat-bite fever, the recommendation would be to include an anaerobic blood culture bottle as the anaerobic bottles contain a lower level of SPS.[70] Certain organisms are so slow growing that they will likely be missed with the routine 5-day incubation time of a standard blood culture; examples of these pathogens are filamentous fungi, *Nocardia* spp., and slow-growing mycobacterial species. Because these microorganisms do require longer incubation times and different media than the routine blood culture provides, it is best to send separate specimens for specialized fungal or mycobacterial testing if these organisms are suspected.

Respiratory Tract Infections

Although the majority of respiratory tract infections have viral causes, the focus of this chapter is on bacterial pathogens. The laboratory diagnosis of respiratory tract infections is complicated by the fact that the respiratory tract is normally colonized with a complex and robust microbiologic community. Importantly, many of the organisms that are normal colonizers of the respiratory tract can also be pathogenic when they are overgrown or out of balance with the normal ecology of the respiratory tract. Common components of normal respiratory flora that are also respiratory tract pathogens include but are not limited to *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, *Neisseria meningitidis*, and *Moraxella catarrhalis*.

For the purposes of laboratory testing, the respiratory tract is divided in two on the basis of anatomy. The upper respiratory tract includes the areas from the anterior nasal passages to the larynx, and the lower respiratory tract includes the structures beyond the larynx. Typically, samples collected from the upper respiratory tract include swabs and washes and are not considered sterile, whereas samples collected from the lower respiratory tract typically require more invasive collection techniques, such as bronchoalveolar lavage or lung biopsy, and may be considered sterile. Because of the difficult and invasive nature of true lower respiratory specimen collection, laboratories often accept specimens that require less invasive techniques, such as expectorated sputa or tracheal aspirates, in an effort to diagnose a lower respiratory tract infection. However, these less invasive specimens are not sterile and must be considered in the context of normal respiratory flora.

Upper respiratory tract infections account for more physicians' office visits than any other type of infection,[13] and although the majority of these infections are the result of viral infections, bacterial causes are also important. Examples of infections that fall into the "upper respiratory" category include pharyngitis, otitis media, and otitis externa.

Diagnosis of pharyngitis can be made by both culture and antigen-based methods. Typically, the specimen is collected on a throat or oropharyngeal swab; swabs made of synthetic fibers are optimal, and there may be an advantage to use of a flocked swab for optimal sample collection.[35] In the pediatric patient population, agents other than *Streptococcus pyogenes* (group A streptococcus) can cause pharyngitis and must be considered. Not all laboratories routinely identify organisms other than group A streptococci, and thus special requests should be made to ensure appropriate testing. In addition to group A streptococci, large colony-forming, β-hemolytic organisms from the Lancefield groups C and G as well as *Arcanobacterium hemolyticum* may cause pharyngitis with clinical symptoms similar to those of group A streptococcal pharyngitis.[78]

Otitis externa and otitis media are usually diagnosed clinically and managed empirically; however, in cases of spontaneous perforation of the tympanic membrane or when tympanocentesis is performed, fluid can be sent for culture and microbiologic evaluation. Fluid is the optimal specimen for bacterial culture. Nasopharyngeal specimens are not representative of the etiologic agents of otitis media.[37]

Laboratory diagnosis of lower respiratory tract infections, primarily pneumonia, is complicated by the difficulty of collecting appropriate lower respiratory tract samples. In addition, delays in transport of specimens to the laboratory may result in overgrowth of significant pathogens by nonpathogenic colonizing flora or the loss of significant pathogens.[14,55] Whereas organisms isolated from specimens such as pleural fluid or tissue from lung biopsy must always be considered significant, these highly invasive procedures are relatively rarely performed. The most common specimens collected to aid in diagnosis of pneumonia include sputa and tracheal washes or aspirates. Results from cultures of these specimen sources in any scenario are complicated by the presence of normal upper airway flora, and the determination of significance for any given isolated organism is difficult.[14] To aid in the determination of the quality of either sputa or bronchial aspirate specimens, laboratories perform microscopy-based screening of specimens and reject samples that are not adequate. Specimen quality is evaluated on the basis of the presence and quantity of organisms, squamous epithelial cells, and polymorphonuclear leukocytes. A large number of squamous epithelial cells represents oropharyngeal contamination, and these specimens should be rejected with a recommendation for recollection (with the exception of cases in which *Legionella* or mycobacterial infections are suspected).[71] The presence of large numbers of polymorphonuclear leukocytes can indicate a quality specimen; however, there are exceptions to this observation. In the case of tracheal secretions or aspirates from ventilated, low-birth-weight infants, large numbers of polymorphonuclear leukocytes were associated with the length of intubation and not the development of respiratory symptoms.[52] Although bronchoalveolar lavage is not as commonly performed because of the more invasive nature of the procedure, bronchoalveolar lavage specimens provide quality lower respiratory tract samples. The procedure includes the wedging of the bronchoscope channel into an airway lumen followed by the injection of saline through the lumen. The injected saline is aspirated out in several aliquots. The initial aliquot removed will be contaminated with upper airway secretions and should be discarded before bacterial culture. In an effort to aid in establishing significance of various pathogens isolated from bronchoalveolar lavage cultures, some laboratories perform quantitative cultures and establish cutoffs for significance.[10]

Central Nervous System Infections

Because of the significant morbidity and mortality associated with bacterial meningitis, the rapid and timely identification of the causative agent is critical. Cerebrospinal fluid (CSF) specimens are collected by lumbar puncture and must be transported to the laboratory at room temperature and processed without delay. Owing to the rapid changes in the pH of the CSF on removal from the patient and the hypotonic nature of CSF, the viability of microorganisms is reduced as time passes, potentially increasing the likelihood of false-negative culture results[24]; in addition, host cells may lyse, resulting in an altered cell count. If sequential tubes of CSF are collected, the first tube is not ideal for microbiologic studies because of the possibility of contamination with skin flora or blood from the initial lumbar puncture, which can alter culture results. The second tube should be sent for microbiologic studies whenever possible. Although bacterial stain and culture can be performed on small amounts of fluid, it is recommended to send larger amounts of CSF because of the typically low number of microorganisms present in the specimen. For isolation of mycobacteria from CSF, a minimum of 5.0 mL of specimen is recommended.[3]

On receipt into the laboratory, CSF specimens should be routinely Gram stained and set up for bacterial culture. Sensitivity of the Gram stain can be improved by concentrating the specimen via cytocentrifugation before staining.[69] Positive Gram stain results can offer useful information about organism morphology and Gram stain phenotype; but large numbers of organisms are needed for visualization, and a negative Gram stain result does not indicate a lack of pathogenic organisms in the CSF.[44] Staining with acridine orange (a fluorescent stain) increases the sensitivity of detection of microorganisms, but this stain does not provide information about the Gram stain phenotype (e.g., gram positive or gram negative).[43,45] CSF specimens should be inoculated onto both chocolate agar and sheep blood agar and incubated for 72 hours. Routine inoculation of broth-based media is not necessary and may result in isolation of contaminants.[54,74] Inoculation of broth media may add value in cases in which anaerobic or other unusual organisms are suspected or when hardware is in place. Direct bacterial antigen testing of CSF by latex agglutination is not recommended.[58]

Urinary Tract Infections

Pediatric urinary tract infections are most commonly caused by gram-negative enteric bacteria. *Escherichia coli* causes 80% of infections. Other common pathogens include but are not limited to *Klebsiella* spp., *Proteus* spp., *Enterobacter* spp., group B streptococcus and *Enterococcus* spp., and occasionally *Pseudomonas* spp.[7,82] As is the case for respiratory tract pathogens, urinary tract pathogens must be isolated and identified in and among a background of other normal bacterial flora. To distinguish organisms that colonize the distal urethra from true urinary tract pathogens, quantitative bacterial culture is performed on urine specimens. To prevent misleading results, it is important that urine specimens be kept refrigerated if they are not inoculated in a timely manner (less than 2 hours); in cases of prolonged storage of urine at ambient temperature, false-positive culture results can be obtained. A midstream, clean-catch, voided urine specimen is ideal; however, these specimens are difficult

to obtain in many pediatric age groups. Catheterized specimens are the ideal choice for patients in whom the clean-catch method is not possible. Soiled diapers and urine collected by affixing a bag to the perineum are not acceptable specimens. Regardless of the specimen, a known volume of urine, 0.001 mL for catheter samples or clean-catch samples, is inoculated onto plate media. This plating technique allows the number of colony-forming units (CFU) per milliliter of urine to be quantified. Current recommendations based on previous studies state that 50,000 CFU/mL of a single uropathogenic organism in a properly collected urine specimen in the presence of pyuria is indicative of a urinary tract infection.[75] Any quantity of bacterial growth from urine collected through a suprapubic aspiration is considered significant.

Gastrointestinal Infections

The most common manifestation of gastrointestinal infection in pediatrics is acute diarrhea, and as is the case with pharyngitis, the most common cause is not bacterial. Viral, parasitic, or immune-related issues most commonly cause diarrhea. However, the ability to rule out a bacterial cause is critical, and thus the clinical microbiology laboratory must have appropriate processes in place to isolate and to identify bacterial stool pathogens. Feces should be collected in a sterile container and transported to the laboratory in a timely fashion to avoid overgrowth with normal flora and the potential loss of pathogenic organisms. If rapid transport to the laboratory is not possible, transport media such as Cary-Blair can be used to stabilize the organisms during transport to the laboratory. Because of the presence of high quantities of commensal flora in feces, stool cultures require a combination of both selective and differential media to identify potential pathogens. Most standard stool cultures will include at least two selective and differential media types; commonly used media formulations for the isolation of pathogens such as *Salmonella* and *Shigella* include but are not limited to MacConkey agar, xylose-lysine-deoxycholate agar, and Hektoen enteric agar. Other examples of media formulated for the detection of specific stool pathogens are cefsulodin-Irgasan-novobiocin (CIN) agar for isolation of *Yersinia* species, thiosulfate–citrate–bile salts–sucrose (TCBS) agar for the isolation of *Vibrio* species, and Campylobacter agar for the isolation of *Campylobacter jejuni* and *Campylobacter coli*. Another important pediatric enteric pathogen is Shiga toxin–producing *E. coli* (STEC); most reported STEC infections in the United States are caused by *E. coli* O157:H7, with an estimated 73,000 cases occurring each year.[51] Non-O157 STEC organisms can also cause diarrheal illness and have been associated with outbreaks and sporadic illness.[40] Direct plating methods for the detection of *E. coli* O157:H7 should be performed on a selective and differential agar, such as sorbitol–MacConkey agar (SMAC), cefixime–tellurite–sorbitol–MacConkey agar (CT-SMAC), or CHROMagar O157. The toxin genes can be detected by molecular methods, or toxin can be detected by enzyme immunoassay after broth enrichment.[36] There is no single definition of what pathogens are routinely screened for in the stool culture. Owing to the variability in the stool culture process, the clinician must inquire as to what pathogens are routinely screened for and which pathogens may require a request for specialized culture methods in the testing laboratory.

NON–CULTURE-BASED DETECTION METHODS

Several non–culture-based approaches are used to detect bacterial infections, including microscopy, detection of bacterial antigens or antibodies against the organism, and detection of nucleic acids by molecular methods. A detailed overview of these detection methods for bacteria is provided in this section.

Microscopy

Direct microscopic observation of the specimen is a simple yet reliable technique for demonstrating the presence of microorganisms as well as inflammatory cells in the specimen. Differential (Gram, Kinyoun, Giemsa) and fluorescent (acridine orange, auramine-rhodamine) stains are most commonly used. The Gram stain is a rapid, inexpensive method for assessing the presence of an etiologic agent in the specimen. Preliminary assessments from a stained specimen can indicate the Gram phenotype (positive or negative), the morphology (cocci vs. bacilli), and the spatial arrangement (clusters, chains, or diploid formation). Other differential stains routinely used for bacterial identification are the Kinyoun stain for *Mycobacterium* spp., the modified Kinyoun stain for *Nocardia* spp. and *Streptomyces* spp., and the Wright-Giemsa stain for bacteria *(Borrelia)* or bacterial inclusions *(Anaplasma*, *Ehrlichia)* in clinical specimens. Fluorescent stains are generally more sensitive than differential stains; however, the Gram phenotype is not available by this type of stain. Although useful information may be collected through a positive direct stain, a negative stain result does not rule out the presence of microorganisms, and thus all direct bacterial stains should be followed by culture.

Molecular Diagnostic Techniques

Molecular techniques have become increasingly important tools for the detection and identification of infectious diseases. The introduction of nucleic acid–based testing has provided increased sensitivity of detection and decreased time to detection for many bacterial pathogens. Molecular tests that are widely used in clinical microbiology can be subdivided into nonamplified and amplified methods.

Nonamplified methods consist of DNA- or RNA-labeled probes that bind to the target nucleic acids and generate a signal from the attached reporter molecule. The probe-based technology is useful for the rapid identification of organisms that already have been enriched

for by culture; the distinct advantage of this method over other amplification-based methods is that there is no risk of contamination of subsequent samples with amplified products. Commercially available examples of probe-based testing include the AccuProbe culture identification test, a rapid DNA probe test that uses the technique of nucleic acid hybridization for the identification of *Mycobacterium tuberculosis* isolated from culture,[2] and peptide nucleic acid probes for the detection of *S. aureus* and *Pseudomonas aeruginosa* from blood culture bottles.[61,63]

Nucleic acid amplification–based tests have become the "gold standard" for the detection of many infectious diseases. Amplification-based methods like polymerase chain reaction (PCR), including variations such as real-time, reverse transcriptase, multiplex, and nested PCR, have the principal advantage of increased sensitivity derived from amplifying the target nucleic acid sequence. The number of pathogens that can be detected by PCR is rapidly increasing. Although nucleic acid amplification–based tests have evolved to include highly complex testing methods, there are also simplified, cartridge-based testing systems available for use in clinical practice, such as the GeneXpert system (Cepheid, Sunnyvale, Calif) for methicillin-resistant *S. aureus* and the Verigene gram-positive blood culture test (Nanosphere, Northbrook, Ill) for identification of organisms from positive blood cultures. Other commercially available, Food and Drug Administration (FDA)–cleared assays use various nucleic acid detection technologies, such as transcription-mediated amplification, strand displacement amplification, ligase chain reaction, nucleic acid sequence–based amplification, and hybrid capture.

Molecular techniques have been particularly useful for the detection and identification of fastidious organisms (those that have specialized growth conditions or are slow or noncultivable under laboratory conditions). There are numerous molecular tests to aid in the identification of poorly cultivable or atypical organisms, including *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Mycobacterium tuberculosis*, *Bordetella pertussis*, *Bartonella henselae*, *Mycoplasma pneumoniae*, and many others. The following paragraphs summarize some of the clinically relevant advances in molecular testing for pediatric patients.

Bordetella pertussis

Although infection with *B. pertussis* can occur at any age, babies younger than 6 months, infants, and young children are at utmost risk.[57] *B. pertussis* infection mostly remains a clinical diagnosis; however, laboratory detection is often sought for confirmation. Isolation of the organism by culture has been the historical standard test for confirmation of diagnosis and is essential if evaluation of antimicrobial resistance is required. However, successful isolation of the organism declines significantly beyond the first 2 weeks of illness and with prior antibiotic therapy.[28,76] Furthermore, *B. pertussis* is fastidious and requires 3 to 6 days of incubation to form detectable colonies by culture. *B. pertussis* often will not grow if cultures are not initiated within 48 hours of sample collection.[48] As per CDC recommendation, detection of *B. pertussis* DNA by PCR has become increasingly available for the timely diagnosis of pertussis.[6] Optimal specimens for PCR testing include nasopharyngeal swabs and aspirates. Throat swabs and anterior nasal swabs have low rates of DNA recovery and should be avoided for *B. pertussis* testing.[6] The increased specificity and rapidity of PCR testing allow the results to be available within 24 to 48 hours. There are currently no FDA-approved *B. pertussis* PCR assays, and there are no standardized protocols, reagents, or reporting formats for *B. pertussis* PCR testing. Consequently, PCR assays vary widely among laboratories. Most *B. pertussis* PCR assays use a single DNA target, the insertion sequence IS481 that is present in multiple copies in the *B. pertussis* chromosome and in fewer copies on the chromosomes of *Bordetella holmesii* and *Bordetella bronchiseptica*.[66] The presence of IS481 in the chromosomes of nonpertussis strains can lead to false positivity.[31] Therefore, interpretation of PCR results should be done carefully in conjunction with evaluation of clinical symptoms.

Tuberculosis

The poor sensitivity of standard laboratory tests for the detection of *M. tuberculosis* is a major obstacle to diagnosis of tuberculosis in children. In addition, the nonspecific clinical presentation, paucibacillary nature of pediatric disease, and inability to expectorate sputum in children further complicate the laboratory diagnosis of tuberculosis.[42] Adequate clinical specimens are often difficult to obtain from children younger than 8 years because of lack of sputum production, and first morning gastric aspirates are an important specimen for pediatric patients.[72] Even with best practice, *M. tuberculosis* is isolated in less than 50% of clinically suspected pediatric cases.[1] Therefore, most cases are still diagnosed on the basis of clinical and radiographic findings. However, rapid laboratory confirmation of tuberculosis can lead to earlier treatment initiation, targeted antimicrobial therapy, and better clinical outcomes.[9] Tests based on nucleic acid amplification have become an important tool for the diagnosis of tuberculosis and, when results are positive, can detect *M. tuberculosis* directly from a specimen with a rapid turnaround time of hours or days in contrast to the weeks required with culture. Whereas the currently available molecular methods are rapid and have excellent specificities, their sensitivities do not equal those of culture-based methods, particularly in cases of smear-negative specimens.[47,59] Unfortunately, most pediatric tuberculosis cases are smear negative.

Several molecular methods for detection of tuberculosis are FDA cleared or approved. The enhanced amplified *M. tuberculosis* direct test (E-MTD; Gen-Probe, San Diego, Calif) and the Amplicor *M. tuberculosis* test (Roche Diagnostic Systems, Somerville, NJ) are FDA approved for detection of *M. tuberculosis* complex in smear-positive respiratory specimens.[47,59] The Gen-Probe test is also approved for use with smear-negative respiratory specimens from patients thought to have tuberculosis. The E-MTD test (isothermal transcription mediated) and the

Amplicor test (PCR based) rely on amplification of a portion of the 16S rRNA followed by hybridization and detection of a probe specific for *M. tuberculosis* complex bacteria. None of these tests has been approved for direct detection from extrapulmonary specimens. There are no specific recommendations made on the use of molecular testing in the diagnosis of tuberculosis in children who cannot produce sputum and in the diagnosis of extrapulmonary tuberculosis.

Clostridium difficile

Laboratory methods for detection of *Clostridium difficile* have undergone considerable evolution since the organism's etiologic association with antibiotic-associated infectious diarrhea and pseudomembranous colitis or *C. difficile*–associated disease in hospitalized patients was established. The diagnostic gold standards for *C. difficile* detection included anaerobic bacterial culture coupled with toxin detection or tissue culture cytotoxic assay, both of which are time-consuming, expensive, and technically challenging.[11] Although rapid detection kits (i.e., immunoassay) are commercially available, they lack sufficient sensitivity and specificity without serial testing.[15,22,27] The emergence of community-acquired *C. difficile* cases without antecedent antibiotic exposure in addition to the emergence of a quinolone-resistant "hypervirulent" strain of *C. difficile* (designated BI/NAP1/027) in adult and pediatric patients led to significant technical improvements in diagnostic laboratory testing.[50,60] One diagnostic approach to the identification of *C. difficile* is to use a rapid, real-time PCR–based molecular assay that targets the disease-producing *C. difficile* toxin genes. Factors that decrease the viability of organisms (e.g., treatment with antibiotics) lower the sensitivity of detection for culture and rapid immunoassays, but loss of viability does not affect molecular assays. There are currently at least six FDA-cleared assays available for detection of *C. difficile*. Most methods are based on real-time PCR with the following exceptions: illumigene *C. difficile* assay (Meridian Bioscience, Cincinnati, Ohio), a loop amplification–based method; and Portrait Toxigenic assay (Great Basin Corp., West Valley City, Utah), an isothermal amplification and chip-based method. All these tests yield results in fewer than 24 hours, with sensitivities reported at greater than 95 percent and negative predictive values of 99 percent.[5,77] However, positive *C. difficile* PCR assays on stool specimens in infants younger than 12 months usually represent colonization, and testing should be performed in infants only when other possible causes of diarrhea have been ruled out.[4]

Neisseria gonorrhoeae *and* Chlamydia trachomatis

Adolescents and young adults have higher rates of infection with *Chlamydia trachomatis* (CT) and *Neisseria gonorrhoeae* (GC) than any other age group does,[62] and nucleic acid amplification testing has greatly facilitated sensitive and specific screening in this population. These assays are extremely sensitive with a limit of detection as low as a single gene copy.[16,33] In addition, testing of urine specimens offers noninvasive sample collection. These tests provide the ability to test for both GC and CT in the same specimen. The most commonly used FDA-approved assays are for testing on cervical swabs from women and urethral swabs and urine from men and women. Importantly, none of these assays is approved for testing of specimens from children. The identification of sexually transmitted diseases like *C. trachomatis* and *N. gonorrhoeae* infections in children should raise suspicion for sexual assault, and there are both medical and legal implications to the diagnosis of sexually transmitted diseases in infants and children.[38] Thus, testing requires the use of a highly specific method; the gold standard for detection of GC/CT in children and infants has been culture from appropriate specimens.[81]

Sequence-Based Technologies

Sequence-based technologies have been used to improve the speed and accuracy of identification of organisms that are difficult to identify by conventional methods or to detect and identify uncultivable organisms. Currently, Sanger sequencing is the most commonly used sequencing method. For bacterial identification, 16S ribosomal genes are common targets of interest.[17] There are several open access ribosomal sequence databases that can be used to produce alignments of the 16S ribosomal sequences and subsequent species assignment. By comparing the organism's 16S rRNA gene sequence with those found in databases of known organisms, the identity of etiologic agents from clinical specimens can be successfully determined.[17,29,39,56] Other technologies, such as pyrosequencing and single-cell and whole genome sequencing methods, are also promising and powerful tools in clinical microbiology.[64,65] Examples of commercially available whole genome sequencing platforms include the SOLiD system (Life Technologies, Carlsbad, Calif) and Genome Sequencer FLX system (Roche Life Sciences, Branford, Ct).[49] These rapid, accurate, and user-friendly methods are able to generate megabases of sequence information about the whole organism. To date, routine application of sequence-based technologies is not widely available in most clinical diagnostic laboratories.

Mass Spectroscopy

Matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF-MS) is a technology that provides rapid identification of a variety of pathogens in clinical specimens within hours.[12,23] This technology uses unique protein spectral profiles of the microorganisms to rapidly identify organisms in clinical specimens from known catalogued databases of these profiles.[21,26,34] In contrast to the culture-based methods of detection and identification of microorganisms, MALDI-TOF-MS allows the detection of bacterial macromolecules in complex mixtures without isolation.[8,53] Although MALDI-TOF-MS is being used by large diagnostic centers to identify various bacterial species from clinical

specimens, it is not currently FDA approved for routine diagnostic testing.[11,30,68,73]

CHAPTER 251

Fungal Laboratory Analysis: Specimen Collection, Direct Detection, and Culture

David A. Bruckner

Fungi were regarded as insignificant causes of infection historically. The most important factor responsible for the increase in the number of fungal infections has been an alteration in the immune response of humans. Organ transplant recipients, particularly during the posttransplantation period, and patients with malignant neoplasms and debilitating immunologic or metabolic disorders, such as systemic lupus erythematosus, diabetes mellitus, and alcohol or injection drug abuse, are particularly susceptible to fungal infections. Opportunistic fungi of low or limited virulence are detected with increasing frequency in subcutaneous or disseminated infections.

SPECIMEN COLLECTION

When an infectious process is suspected, the most appropriate tests directed toward the detection of the etiologic agent must be ordered by the physician. Knowledge of the pathophysiology of the disease process is important in determining the optimal time for specimen collection. These collections include specimens for culture, direct detection of the etiologic agent with antigen tests, nucleic acid detection, stains, and antibody methods.[1,3,4,6,8-11] All specimens should be considered hazardous, and universal precautions must be used for all specimen collection procedures. A sufficient quantity of a specimen must be obtained for the techniques required to detect the fungal agent directly, for culture, for antigen detection, or for serology. Procedures used for specimen collection for culture of bacteria also can be used for culture of fungi (Table 251-1). Microbiologists and pathologists are available to guide physicians in selecting the most appropriate specimen for culture and other tests to achieve rapid detection and recovery of the microorganism causing the infection. Most clinical laboratories have established guidelines for specimen collection with minimal volumes of specimen to be collected. In addition, specimens should be collected in sterile containers before the initiation of therapy to ensure that optimal recovery of organisms is achieved. An important factor is that adequate specimen volumes, which include up to 5 mL of cerebrospinal fluid (CSF) and 200 mL of urine for fungal culture, be submitted to the laboratory. Specimens collected for 24 hours, such as urine and sputa, are unsuitable for fungal culture because of bacterial overgrowth. Swab specimens are considered inadequate for the recovery of fungi, particularly when multiple culture tests (bacteriology, mycology, mycobacteriology, and virology) from the same swab specimen are requested. In many instances, surgeons send tissue for a histologic diagnosis and neglect to submit a request for culture. If an infection caused by a dimorphic fungus such as *Coccidioides immitis* is suspected, the physician should notify the laboratory because of hazards associated with culture of this organism. A poorly collected specimen may result in the failure to recover the organism, or it may lead to therapy directed at a contaminating or commensal organism.

Specimens should be transported to the laboratory as soon as possible under optimal conditions, which usually are advised in the laboratory specimen collection manual that should be available to all physicians. Specimen transport and storage at room temperature is recommended. Ideally, specimens should be received in the laboratory within 2 hours of being collected. If a delay occurs in setting up cultures, the specimen should be held at room temperature or 4°C (39.2°F) to prevent bacterial overgrowth. Unacceptable specimens that should not be processed include specimens in containers that leak, specimens received many days after collection, and specimens held under inappropriate temperature conditions. Some fungal isolates, such as *Cryptococcus neoformans* and *Histoplasma capsulatum*, do not survive well at refrigerated or freezing temperatures.

DIRECT DETECTION

In the laboratory, direct wet mounts or smears can be prepared and a portion of the specimen can be used for culture (Table 251-2). Blood, CSF, and urine also can be used for the detection of antigens and nucleic acids by enzyme immunoassay, latex agglutination, polymerase chain reaction, and radioimmunoassay.[2,6-8] These assays have proved to be useful for the detection of infections caused by *Aspergillus*, *C. neoformans*, and *H. capsulatum*.[2] Although polymerase chain reaction techniques may be used for the direct detection of fungal infections, they are used in research or have been validated in specific laboratories for clinical use but are not readily available in most clinical laboratories.[5] Direct microscopic examination, including frozen sections of tissue to provide an

TABLE 251-1 **Specimen Collection Guidelines**

Specimen	Recommendations	Transport Device/Comments
Abscess/wounds	Collect as per bacterial culture.	Collect in sterile container with as much material as possible. If swab is used, use exclusively for mycology. RT
Blood	Collect as per bacterial culture.	BacT/Alert, BACTEC, VersaTREK, or Septi-Chek (biphasic) bottles. Isolator (lysis-centrifugation). RT, never refrigerate
Bone marrow	Collect as per bacterial culture.	Collect in sterile container, Isolator, or heparin (green top) tube. If clotted, may have to homogenize or cut into pieces to place on mycology media. RT
CSF	Collect as per bacterial culture. Fluid volumes greater than 1 mL should be centrifuged or filtered.	Collect in sterile container. RT, never refrigerate
Eye	Corneal scrapings should be inoculated directly onto mycology media. Vitreous fluid should be collected by needle aspiration.	Direct inoculation onto mycology media without cycloheximide. Vitreous fluid can be placed in a sterile container, or the syringe with needle removed can be sent to the laboratory. RT
Fluids other than CSF and urine	Collect as per bacterial culture. Fluid volumes greater than 1 mL should be centrifuged or filtered.	Collect in sterile container. RT
Hair	Can use Wood lamp to help select infected hairs. Also scrape border of infected area if lesions are present.	Place 10-12 hair roots in sterile container. RT
Nails	Swab surface with 70% alcohol. Collect softened material from beneath nail bed.	Use sterile container or directly inoculate mycology media. RT
Prostatic secretions	Empty bladder before giving prostate massage. For detection of *Blastomyces* and less commonly *Coccidioides, Cryptococcus,* and *Histoplasma.*	Place in sterile container or directly inoculate mycology plates. RT
Respiratory	Collect as per bacterial culture using same rejection criteria for sputum. Early morning sputum is the preferred specimen.	Use sterile container. RT
Skin	Disinfect surface area with 70% alcohol to remove bacterial contaminants. Scrape skin surface at the edge of the lesion.	Use sterile container or directly inoculate mycology media. RT
Tissue/biopsy	Collect specimen per surgical technique.	Sterile container to which a small amount of sterile saline or water may be added to keep tissue moist. RT
Urine	Collect as per bacterial culture. Early morning specimen is preferred. Use midstream collection technique.	Use sterile wide-mouthed container. RT
Vaginal	Collect specimen as per bacterial culture. Primarily for *Candida* infections.	Swab transport device. RT

CSF, cerebrospinal fluid; RT, room temperature.

immediate presumptive diagnosis, should be performed on most specimens. A definitive diagnosis may be made when specific fungal elements pathognomonic for fungal infections are detected in direct specimen stains. Examples include *Blastomyces dermatitidis*, *Cryptococcus neoformans*, *Coccidioides immitis*, and *Pneumocystis jiroveci*. Detection of wide and narrow, wavy, or ribbon-like nonseptate hyphae is consistent with a mucormycosis. Direct specimen examinations always must be followed with culture because the direct examination can never be used to rule out infection, and recovery of the organism may be necessary for speciation.

Serology may be used to diagnose fungal infections either because other direct detection methods were negative or the organism failed to grow in culture. In general, serology is not as sensitive as are other direct methods, such as antigen detection, particularly in immunocompromised patients. Serology has been useful in the diagnosis of *C. immitis* and *H. capsulatum* infections and can be used to follow successful therapy in coccidioidomycosis.[7] Serologic methods include complement fixation, enzyme immunoassay, immunodiffusion, and latex agglutination.

During infections, fungal cell wall antigens are released into surrounding tissue and body fluids (blood, CSF, respiratory secretions, and urine).[7] The results from antigen tests are much more rapid than culture. Their detection can be useful in supporting a clinical diagnosis when culture and histopathology are negative. Detection of glucuronoxylomannan has been successfully used to diagnose and follow *C. neoformans* and *Cryptococcus gattii* infections. This test is highly sensitive, and circulating

TABLE 251-2 **Methods for Detection of Fungi in Human Specimens**

Stain/Method	Use	Comments
Aspergillus galactomannan EIA, β-D-glucan EIA	To detect galactomannan or polysaccharide cell wall component in serum or fluid	An EIA test is used as an adjunct to culture for the detection of *Aspergillus* or *Candida* in high-risk patients. The test has low sensitivity and specificity. β-D-Glucan is found in most fungi, whereas the galactomannan test is used to detect aspergillosis.
Acid-fast, modified	To detect *Nocardia*	Most *Nocardia* will stain pink.
Calcofluor white	Binds to chitin and cellulose of fungal cell wall	Rapid detection of fungi and *Pneumocystis*. Staining time is 1 minute; requires fluorescent microscope. Organisms fluoresce blue-white. May be used with Evans blue to suppress background fluorescence.
Cryptococcal antigen test (EIA)	Detects antigen in CSF and blood	A reliable and sensitive method for the detection of cryptococcal antigen. Can be used to monitor therapy.
Fontana-Masson	Detects *Cryptococcus* and other dematiaceous fungi	Stains melanin black or dark brown.
Giemsa	Stains most bacteria and fungi	Used for the detection of *Histoplasma* and *Penicillium marneffei* in blood and bone marrow. *Pneumocystis* trophozoites and intracystic sporozoites can be detected. Organisms stain blue-purple.
Gridley	Stains fungal cell wall	Cell wall stains purple-red with yellow background.
Gomori methenamine silver	Stains most organisms in tissue	Fungi including *Pneumocystis* cysts stain gray-black. Difficult to control staining reaction and may be difficult to interpret because of background staining.
Gram	Used primarily for detection of bacteria	Yeast cells and pseudohyphae stain gram-positive; *Cryptococcus* stains gram-positive surrounded by a capsular halo; hyphae will stain gram-negative.
Hematoxylin and eosin	Used to demonstrate patient's tissue reactions	Fungi stain violet to blue-purple. Can see fungal pigments.
Histoplasma urine antigen (EIA)	To identify infections of *H. capsulatum*	More sensitive and faster than culture. Test can cross-react with *Coccidioides immitis* and other dimorphic fungi.
India ink	To detect *Cryptococcus* in CSF specimens	To help detect capsule of *Cryptococcus neoformans*. Not very sensitive, and capsule may be difficult to detect.
Mucin (Mayer or Southgate mucicarmine)	Stains mucopolysaccharide or fungal capsule	Cryptococcal capsule stains red.
Papanicolaou	Used to detect the presence of malignant cells	Fungal elements stain pink. Some fungi may not stain.
Periodic acid–Schiff	Stains glycogen, mucin, mucoproteins, and glycoprotein	A mucin stain used to stain the capsular mucopolysaccharide of fungal organisms. Capsule will have a pink-magenta or purple color.
Pneumocystis DFA	Detects *Pneumocystis* cysts and trophozoites	Rapid staining method specific for *Pneumocystis* in respiratory specimens.
PCR	Can be used for direct detection of fungal pathogens	Not commercially available but has been developed in specific diagnostic laboratories for the detection of selected fungal pathogens.
Potassium hydroxide	To detect yeast and hyphal elements in wet mounts	Used as a clearing agent to make fungi more visible in tissue, hair, nails, and body fluids. Digests proteinaceous material of host cells, leaving fungi intact.
Wright	Stains most bacteria and fungi	Used for the detection of *Histoplasma* and *Penicillium marneffei* in blood and bone marrow. *Pneumocystis* trophozoites and intracystic sporozoites can be detected. Organisms stain blue-purple.

CSF, cerebrospinal fluid; DFA, direct fluorescent antibody; EIA, enzyme immunoassay; PCR, polymerase chain reaction.

capsular polysaccharide can be quantitated to determine a patient's therapeutic response. Invasive aspergillosis is a diagnostic challenge, and the development of a galactomannan test (polysaccharide cell wall component of *Aspergillus*) had been helpful in certain patient populations. The test results have better predictability among patients with hematologic malignant disease than among those receiving a solid-organ transplant. False-positive test results are common in lung transplant patients. Urine antigen tests for the diagnosis of histoplasmosis and blastomycosis are sensitive and more rapid than culture or serologic results. Other fluids can be used with these tests for detection of blastomycosis and histoplasmosis, but the test may have to be validated by the laboratory before the results can be used clinically. β-D-Glucan is a major cell wall component of most fungi with the exception of *Mucorales* and low amounts in *Cryptococcus* and *Blastomyces.* This serum antigen has been used as a diagnostic marker for invasive fungal infections. False-positive test results for β-D-glucan and galactomannan have occurred in patients exposed to products containing these polysaccharides.

Nucleic acid tests for the detection of fungal pathogens may be available in specialized reference centers, but none is approved by the Food and Drug Administration for routine clinical diagnosis.[8]

PRIMARY ISOLATION MEDIA

The most reliable and sensitive means for diagnosis of a fungal infection is isolation of the organism on culture media.[1,3,9-11] A variety of media are commercially available for primary isolation of fungal organisms (Table 251-3). The medium chosen should support the growth of fungal isolates while inhibiting bacterial organisms from specimens collected from nonsterile sites. Traditional antibiotics used include chloramphenicol, gentamicin, penicillin, and streptomycin. Antibacterial agents can inhibit actinomycetes; therefore, media without antibiotics should be chosen if this agent is suspected, or a combination of media with and without antibiotics could be used.

Media may use cycloheximide, a protein synthesis inhibitor, to suppress the growth of saprophytic fungi. It also inhibits *Aspergillus*, *Candida*, *Cryptococcus*, *Trichophyton*, and most *Mucorales*. Cycloheximide can be used in combination with various antibacterial agents listed earlier.

Chromogenic media are useful for the recovery and identification of *Candida* spp.[5] Dermatophyte test medium (DTM) was designed specifically for the culture and isolation of dermatophytes. Other media used can be those

TABLE 251-3 **Primary Isolation Media**

Media	Supplements	Use
CHROMagar, Candida or Albicans ID agar	Chromogenic substrates and antibiotics	Selective and differential medium for recovery of clinically important yeasts. Assimilation of chromogenic substrates and colony color development allow presumptive identification of common *Candida* species. *Candida* species detected is manufacturer dependent.
Dermatophyte test medium	Chloramphenicol, cycloheximide, gentamicin	Selective and differential medium for recovery of dermatophytes *(Epidermophyton, Microsporum, Trichophyton).* Medium turns from yellow to red with growth of dermatophytes.
Inhibitory mold agar (IMA)	Chloramphenicol; gentamicin may be added	Selective and enriched medium used to isolate cycloheximide-sensitive fungi *(Candida, Cryptococcus, Histoplasma, Zygomycetes,* some *Aspergillus)* and inhibit bacterial growth.
Mycosel	Chloramphenicol and cycloheximide	Selective medium for isolation of dimorphic fungi and dermatophytes. Chloramphenicol inhibits bacterial growth and cycloheximide inhibits rapidly growing molds and yeasts.
Potato flake agar	Can be made selective by addition of chloramphenicol and cycloheximide	Useful for production of conidia and pigment.
Sabouraud brain-heart infusion agar (SABHI)	Used with (selective) or without antibiotics. Antibiotics include chloramphenicol, ciprofloxacin, cycloheximide, penicillin, and streptomycin. Could add sheep blood for recovery of *Histoplasma.*	General purpose medium for growth of dimorphic and other fungi.
Sabouraud dextrose agar (SDA)	None	General purpose medium supporting growth of aerobic actinomycetes and all fungi.
	Addition of olive oil on surface	Selective for cultivation of *Malassezia furfur.*
Yeast extract phosphate medium	Ammonium hydroxide and chloramphenicol	Selective medium promotes recovery of slow-growing dimorphic fungi. Chloramphenicol inhibits bacterial growth and ammonium hydroxide inhibits growth of other fungi.

containing caffeic acid for the detection of *C. neoformans* by its phenol oxidase activity or media overlaid with olive oil (long-chain fatty acid source) for the recovery of *Malassezia furfur*.

When processing tissue, avoid the use of a mortar and pestle or tissue grinder. Hyphal elements, particularly aseptate hyphae, are easily destroyed in this process, rendering culture recovery impossible. Recommendations are to mince the tissue with a scissors or scalpel blade into 1-mm cubes and to place these fragments onto the agar surface.

Nonselective media will permit the recovery of rapidly growing yeast and fungi as well as of fastidious, slow-growing fungi. Selective media will enhance the recovery of slower-growing dimorphic fungi while inhibiting the faster-growing yeast and fungi that may contaminate the medium and render isolation of the slower-growing organisms impossible.

In general, a battery of media, including media containing sheep blood (BHI and Sabouraud brain-heart infusion agar [SABHI]), is used for the recovery of fungal isolates. Although sheep blood inhibits conidiation, it does improve the recovery of fungal isolates. Agar plates or screw-capped tubes can be used for isolating fungal isolates. Most mycologists prefer agar plates because of the ease of handling the cultures, and the larger surface area provides for better isolation of colonies. Plates usually are sealed with air-permeable tape or shrink-wrap to prevent inadvertent opening of the plate and also to slow down or to retard dehydration of the media because many plates are held for 4 weeks in the laboratory before the specimen is signed out as negative. Examination of culture plates or agar tubes should be performed in a certified biologic safety cabinet. Most fungi will grow on routine bacteriology plates; however, the incubation time usually is short and may not allow sufficient time for the fungi to grow and be visually noticed on the plates.

CHAPTER 252

Viral Laboratory Diagnosis

Romney M. Humphries • Marjorie J. Miller

In the past, diagnostic testing for viral agents consisted primarily of isolation of virus in tissue culture and serologic studies. These tests were often perceived as too impractical, nonproductive, and slow to warrant implementation in the hospital laboratory. Fortunately, in recent years technologic developments and an expanding commercial availability of reagents and test kits have enabled laboratories to provide effective virologic diagnostic services with turnaround time to results and charges similar to those for other areas of the microbiology laboratory.[84,85,125,153] Although an increasing number of these reagents are being approved or licensed as in vitro diagnostic devices, a major hurdle to adding these technologies to laboratory test menus is the requirement that the laboratory verify manufacturer-established performance characteristics for each test, before implementation. Such verification studies often are extensive and taxing to laboratory resources, although manufacturers may offer educational and technical support to assist the laboratory, if permitted by local regulations. Practical guidance for verification studies has been published elsewhere.[20,60,163]

Presently, virologic services offered by clinical laboratories may range from referral of specimens to a reference laboratory to limited detection of viral antigens (e.g., respiratory syncytial virus, influenza, adenovirus, rotavirus) or expansion to include culture and qualitative and quantitative molecular assays. This chapter presents the general aspects of diagnosis of viral infections, including specimen selection, collection, and transport; conventional and modified culture for virus isolation and identification; and rapid detection of viral antigens and nucleic acids directly in specimens. Specific aspects of diagnosis are presented in the respective chapters covering the viral agents.

SPECIMEN COLLECTION AND TRANSPORT

Laboratory diagnosis of viral infections depends primarily on the collection of appropriate specimens, in sufficient volume, at the correct time during the course of the illness using optimal transport and storage conditions. Improvements in the sensitivity and accuracy of laboratory assays will be rendered insignificant if preanalytical considerations are overlooked.

Specimen Collection Sites

The selection of appropriate specimens as early in the acute phase of the illness as possible is critical to the recovery of viruses. A guide to recommended collection sites for specific viral syndromes is presented in Table 252-1. In general, the extent of the diagnostic investigation should be dictated by the characteristics of the illness being studied. For example, in common respiratory illnesses such as pharyngitis or croup, collection of a single specimen from the throat usually is sufficient. In other situations in which an illness is severe or unique, collection of specimens from multiple sites is important. In addition, in unusual cases, serum should be obtained for frozen storage in case subsequent serologic studies are required.

In severe illnesses, invasive procedures (e.g., brain, cardiac, liver, lung biopsies, and needle aspiration of body fluids) frequently must be performed to obtain material for laboratory study. Many medical specialists argue against using these invasive procedures because little can be done to treat viral illnesses. However, in our experience, the knowledge gained from a positive viral identification justifies some risk incurred in collecting specimens. At present, antiviral drugs are similar to antibacterial and antifungal agents in that they generally can be used effectively only after definitive identification of the etiologic agent. Demonstration of a viral etiology in diseases such as encephalitis, pneumonia, or cardiac disease can prevent the unnecessary administration of antibiotics and steroids. In many cases, overuse of services, patient trauma, and overall cost can be reduced when a viral agent is confirmed. Finally, the prognosis of a particular illness is more accurate when the specific etiology is known.

Collection of Specimens

Specimens for virus culture or direct examination are generally obtained as they are for other microbiologic studies. The primary purpose of a transport medium is to provide a protective protein, neutral pH, and antibiotics for control of microbial contamination and, most importantly, prevention of desiccation. Many viral transport and storage media are available commercially; their utility has been reviewed elsewhere.[52,97] Saline or holding media that contain serum should be avoided. Useful liquid transport media (i.e., 2-mL aliquots in screw-capped vials) consist of tryptose phosphate broth with 0.5 percent bovine albumin; Hanks balanced salt solution with 5 percent gelatin or 10 percent bovine albumin; or buffered sucrose phosphate (0.2 mol/L, 2-SP),[87,97] which has been used as a combined transport medium for viral, chlamydial, and mycoplasmal culture requests[184] and is appropriate for long-term frozen storage of specimens and isolates.[87] Many of these transport media also have been evaluated and found acceptable for use in rapid methods (e.g., enzyme-linked immunosorbent assay [ELISA][144,202] and nucleic acid amplification tests [NAATs]).[131]

Convenient and practical collection devices, such as UTM Kits (Copan), or Universal Viral Transport Kits (Becton Dickenson), consist of a swab, usually a nylon flocked swab on a plastic shaft, and a self-contained transport medium. Calcium alginate swabs, which are toxic to herpes simplex virus (HSV), and wooden shafts, which may be toxic to viruses and the cell culture system itself, should not be used. Nylon flocked swabs should be used over traditional swabs whenever possible, because these are associated with both enhanced absorbance to, and subsequent release of, specimen from the swab.

Throat

Specimens from the throat should be obtained with a swab in a manner similar to that used for bacterial culture. The posterior pharyngeal wall and tonsillar surfaces, any inflamed or erythematous areas, and any visible lesions are swabbed firmly without contact with the tongue and anterior oral cavity.

Nose and Nasopharynx

Specimens should be collected with nasopharyngeal swabs that have thin, flexible shafts by inserting the swab into the nasopharynx and rotating it to obtain the maximal number of ciliated, columnar epithelial cells and then placing the swab in transport medium. Alternatively, nasopharyngeal secretions can be obtained from infants by nasal washing.[82] In this method, a small amount of sterile phosphate-buffered saline (3 to 7 mL) is squeezed into the nose with a nasal bulb aspirator (1 oz, tapered) and then immediately withdrawn and placed in a sterile, screw-capped container. Nasopharyngeal aspirates also may be obtained with a mucus collection device. An appropriately sized catheter is inserted nasally into the posterior of the nasopharynx; intermittent suction is applied as the catheter is withdrawn. Aspirate is washed through the tubing with 5 to 8 mL of transport medium or sterile phosphate-buffered saline. Nasopharyngeal washes and aspirates may be placed into a viral-specific transport medium, which may enhance sensitivity of both direct antigen tests and molecular methods.[26] Washes and aspirates (vs. traditional swabs) are preferred for direct antigen detection because more epithelial cells are obtained by this method.[46] However, the enhanced absorbent capacity of flocked swabs over traditional swabs for exfoliated virus-infected epithelial cells, when combined with the relative ease of collection of a nasopharyngeal swab in contrast to an aspirate or wash, make flocked swabs an attractive option, particularly for very young patients. Nasopharyngeal specimens collected using

TABLE 252-1 **Specimen Collection Guide for the Diagnosis of Viral Infections Based on the Viral Syndrome and Etiologic Agent Suspected**

Main Location or Category of Illness	Clinical Diagnosis	*Specimen Collection Source*			Etiologic Agent Suspected*
		Most Practical	Most Definitive	Other Sources	
Upper respiratory tract	Common cold, nasopharyngitis	Nasopharynx/nose	Nasopharynx/nose	Nasopharyngeal/nasal wash, stool, blood	Rhinoviruses, coronaviruses, parainfluenza viruses, RSV, enteroviruses, adenoviruses
	Pharyngitis	Throat	Throat	Stool, blood	Adenoviruses, enteroviruses, Epstein-Barr virus, influenza viruses, parainfluenza viruses
	Herpangina, other enanthems	Throat	Lesions	Stool, blood	Enteroviruses, HSV
	Laryngitis, laryngotracheitis	Throat	Larynx or trachea	Nasopharyngeal/nasal wash	Parainfluenza viruses, influenza viruses
	Parotitis, other salivary gland enlargement	Throat	Stensen duct	Urine, blood, cerebrospinal fluid	Mumps virus, enteroviruses
Lower respiratory tract	Bronchitis, bronchiolitis, pneumonia	Throat	Bronchoalveolar lavage, bronchial washing biopsy	Stool, blood, sputum, nasopharyngeal/nasal wash	RSV, human metapneumovirus, parainfluenza viruses, adenoviruses, influenza viruses, cytomegalovirus
	Pleurodynia	Throat	Throat	Stool	Enteroviruses
	Pleural effusion	Pleural fluid	Pleural fluid	Throat, stool, blood	Enteroviruses, adenoviruses
Heart	Myocarditis, pericarditis, conduction defects	Throat	Pericardial fluid, biopsy	Stool, blood, urine	Enteroviruses, influenza viruses, adenoviruses
Central nervous system	Meningitis	Throat	Cerebrospinal fluid	Stool, blood, urine	Enteroviruses, mumps virus, arboviruses, HSV-2, lymphocytic choriomeningitis virus
	Encephalitis	Throat	Brain biopsy	Cerebrospinal fluid, stool, blood, urine	Arboviruses, mumps virus, enteroviruses, HSV-1, influenza viruses
	Guillain-Barré syndrome, cerebellar ataxia, transverse myelitis, poliomyelitis	Throat	Throat	Stool, blood, cerebrospinal fluid	Influenza viruses, arboviruses, enteroviruses, Epstein-Barr virus
Genital tract	Orchitis, epididymitis	Throat	Testicular biopsy	Stool, blood, urine	Mumps, enteroviruses, lymphocytic choriomeningitis virus
	Herpes genitalis	Lesions	Lesions	Vagina, cervix, urethra	HSV
Urinary tract	Cytomegalovirus infection	Urine	Urine	Throat, blood	Cytomegalovirus
	Hematuria and/or pyuria	Throat, urine	Urine	Blood, stool	Arboviruses, enteroviruses, mumps virus, adenoviruses
Gastrointestinal tract	Nausea and/or vomiting	Throat	Throat	Stool, blood	Enteroviruses, influenza viruses, noroviruses
	Diarrhea	Stool	Stool	Throat	Rotaviruses, enteroviruses, adenoviruses, noroviruses
	Abdominal pain	Throat	Throat	Stool, blood	Enteroviruses, adenoviruses

	Acute abdomen mesenteric adenitis	Throat	Mesenteric lymph node biopsy, peritoneal fluid	Stool, blood	Enteroviruses, adenoviruses
	Hepatitis	Throat	Liver biopsy	Stool, blood	Hepatitis A, B, C, E, and G viruses, Epstein-Barr virus, adenoviruses, enteroviruses, cytomegalovirus
	Pancreatitis	Throat	Duodenal fluid	Stool, blood	Enteroviruses
	Reye syndrome	Throat	Liver biopsy	Blood	Influenza viruses, varicella virus
	Hepatosplenomegaly	Throat	Blood, liver biopsy	Stool, urine	Adenoviruses, enteroviruses, Epstein-Barr virus, cytomegalovirus
Reticuloendothelial system	Generalized lymphadenopathy	Throat	Blood, lymph node biopsy	Stool, urine	Adenoviruses, enteroviruses, Epstein-Barr virus, cytomegalovirus
	Immunodeficiency	Blood	Blood	Lymph nodes	HIV
Bone or joints	Osteomyelitis	Bone	Bone	Throat, blood, urine, skin lesion	Rubella virus, vaccinia virus
	Arthritis	Joint fluid	Joint fluid	Throat, blood, urine	Rubella virus, arboviruses
Muscle	Myositis	Throat	Muscle biopsy	Stool, blood	Influenza virus, enteroviruses
Skin	Exanthematous disease	Throat	fluid, skin biopsy Vesicular	Stool, blood, urine, eye	Measles virus, rubella virus, varicella virus, enteroviruses, HSV
Eye	Conjunctivitis, including pharyngoconjunctival fever	Conjunctiva	Conjunctiva	Throat, stool	Adenoviruses, enteroviruses
Eye	Keratoconjunctivitis	Conjunctiva, cornea	Conjunctiva, cornea	Throat, stool	Adenoviruses, herpes simplex virus, varicella virus
	Retinitis	Vitreous, aqueous fluid	Vitreous, aqueous fluid		Cytomegalovirus, herpes simplex virus, varicella virus
Fever	Nonspecific febrile illness (human-to-human transmission)	Throat	Blood	Stool, urine, cerebrospinal fluid	Enteroviruses, influenza viruses, adenoviruses, cytomegalovirus
	Nonspecific febrile illness (arthropod vector)	Blood	Blood	Throat, urine, cerebrospinal fluid	Arboviruses
	Fever of unknown origin	Blood	Blood	Urine, stool, throat	Hepatitis A, B, C, E, and G viruses, cytomegalovirus, herpes simplex virus, Epstein-Barr virus, adenoviruses
Congenital infection	Rubella virus, cytomegalovirus infections	Throat	Blood	Urine, nasopharynx, biopsy material, cerebrospinal fluid	Rubella virus, cytomegalovirus
	HIV infection	Blood	Blood	Lymph node	HIV
Perinatal and neonatal infections	Herpes simplex virus, cytomegalovirus, enterovirus infections	Throat	Blood	Urine, nasopharynx, stool, skin lesions, cerebrospinal fluid	Enteroviruses, RSV, influenza viruses, herpes simplex virus, cytomegalovirus

*This list includes only the more commonly associated agents. It is likely that with more general use of viral diagnostic services, new virus–disease associations will be made.
HIV, Human immunodeficiency virus; *RSV,* respiratory syncytial virus, *HSV,* herpes simplex virus.

flocked swabs yield sensitivity equivalent to that of aspirates for direct antigen detection[3,26] and in many cases, better sensitivity for polymerase chain reaction (PCR)-based methods.[134,207]

Other Respiratory Specimens (Sputum, Tracheal Aspirates, Bronchial Washings, Bronchoalveolar Lavage)

Collection depends on the volume obtained. Volumes of 0.5 mL or larger should be placed in a sterile container and sealed tightly. If the volume is less than 0.5 mL, the specimen is placed in 2 mL of transport medium.

Eye

Exudate or pus should be removed first with a sterile swab. Conjunctival specimens may be obtained by pressing a swab premoistened with sterile saline firmly against the inflamed areas. The swab is returned to the self-contained transport device. Corneal scrapings should be obtained by an ophthalmologist or other trained person and placed in transport medium immediately.

Body Fluids Other Than Blood

Body fluids such as urine (clean voided, 10 to 20 mL), cerebrospinal fluid (CSF) (2 to 5 mL), pleural effusion, and peritoneal, pericardial, or joint fluid should be collected under sterile conditions and placed in securely sealed, sterile containers. For small volumes (≤0.5 mL), the specimen may be placed in transport medium.

Lesions

For lesions, fresh vesicles should be selected because recovery of virus from older lesions decreases significantly. They should be gently swabbed with sterile saline. The vesicle is ruptured and both fluid and cells collected from the base of the lesion. Material obtained from several lesions may be pooled. Desiccation must not be allowed to occur; swabs should be submitted moistened with their self-contained transport medium or, if that is unavailable, placed in 2 mL of transport medium. Specimens may be collected with a swab or aspirated with a 26-gauge needle attached to a tuberculin syringe. Aspirated fluid should be rinsed into 1 to 2 mL of transport medium.

For direct antigen detection by immunofluorescence (direct fluorescent antibody [DFA]), the vesicle is ruptured as previously described and epithelial cells are collected by firmly swabbing the base of the lesion. Cells are transferred to a clean glass slide by firmly rolling the swab back and forth over a 5- to 10-mm area (dime size) or, if a ringed slide is used, into the center of the ring. For differentiation of HSV types 1 and 2 (HSV-1 and HSV-2) and varicella-zoster virus (VZV), three slides should be prepared.

Stool and Rectal Specimens

Fecal specimens should be collected only when the specific primary diagnosis is diarrhea or when concomitant serologic study with paired sera can be performed. Both enteroviruses and adenoviruses can be recovered readily from stool, but because these agents are carried in the lower gastrointestinal tract for considerable periods of time after acute infection, use of this source for establishing the diagnosis of specific illnesses is limited.

For recovery of enteroviruses, fresh stool specimens are better than rectal swabs; 2 to 5 g (2-3 tsp) of formed or liquid specimen should be transferred to a sterile, leakproof container. However, from a practical point of view, a rectal swab is the simplest method of specimen collection. A rectal swab can be obtained immediately, whereas collection of a stool specimen usually entails considerable delay. Of importance is that the swab contain visible stool; the swab should be inserted 3 to 5 cm into the rectum, rolled against the mucosa, and then transported in transport medium.

Blood

Some viruses can be recovered from serum or red blood cells (RBCs), but in general, leukocytes are a better source of virus. Fresh blood (optimally 5 mL) is collected in a suitable anticoagulant (i.e., heparin, ethylenediaminetetraacetic acid [EDTA], or acid citrate dextrose) and transported to the laboratory for processing by density gradient [132] centrifugation or other methods to enrich for leukocytes. EDTA is the anticoagulant of choice because it is an acceptable transport for culture, as well as for molecular methods such as hybridization and PCR.

Bone Marrow

Approximately 2 mL should be aspirated into a tube or syringe containing heparin anticoagulant, mixed thoroughly to prevent clotting, and transported without further additives or diluents.

Biopsy Specimens

For biopsy specimens, fresh tissue obtained from the affected site should be placed in 2 mL of transport medium to prevent desiccation.

Autopsy Specimens

Most postmortem specimens are almost useless for viral cultivation because of the manner in which autopsies usually are performed. If labile agents are to be recovered, the autopsy should be performed within 4 hours of death. All tissues (as 1- to 2.5-cm cubes) for study should be obtained aseptically, and individual tissue should be collected with sterile instruments and placed in separate sterile containers. Because the usual autopsy routine entails fixation of specimens, of vital importance is that specimens for viral isolation not be placed in containers with fixatives such as formalin or other preservatives.

Transport to the Laboratory

The method of handling specimens from the time of collection to laboratory processing is critical not only for

preservation of virus infectivity for recovery in culture but also for optimal preservation of nucleic acid integrity before molecular detection methods. In general, the less time that transpires between collection and processing by the laboratory, the greater is the chance of detecting the virus. Specimens should not be frozen or exposed to temperatures higher than 22° C (71.6° F). For short-term storage (<5 days) of most viruses, the specimen should be held at 4° C (39.2° F) until it can be processed in the laboratory. For transport to the laboratory, this temperature can be achieved with the use of cold packs or ice. Transport of specimens at 4° C is less critical for testing by molecular-based assays, provided an appropriate transport medium is used and the delay is not greater than one day.[50]

When considerable delay between collection and culture will elapse (e.g., transport to other laboratories, holiday schedules, and so on), special preparation is necessary. Such preparation needs to be individualized and based on the most likely viral cause of a particular illness. For example, when an enteroviral etiologic agent is suspected, freezing the specimen (–70° C [–94° F]) and shipping it with dry ice are satisfactory. In contrast, a urine specimen from a patient with possible cytomegalovirus (CMV) infection should not be frozen. It should be shipped under wet ice at 4° C (39.2° F) because CMV in urine is stable for several days at this temperature. In addition, media that protect viruses against the deleterious effects of temperature fluctuations, particularly freeze-thawing, are available for transport and long-term storage.[87,97] For specific characteristics of individual viruses, see the respective chapters in this book.

LABORATORY DIAGNOSIS OF VIRAL INFECTIONS

In recent years, rapid technologic advances have provided powerful and achievable methods for the detection of viruses in clinical specimens. Direct detection of viral antigens such as the herpes group viruses (HSV, VZV, CMV); respiratory syncytial virus (RSV); influenza viruses; adenoviruses; and rotaviruses, usually by DFA testing, has become routine and has made obtaining same-day or next-day results a reality. In addition, detection of viral antigens in cell culture by the application of immunofluorescence or immunoperoxidase staining, before the appearance of cytopathic effect, has greatly reduced the time needed to report a positive result. More recently, widespread availability of commercial reagents and kits for molecular detection and quantitation of viral nucleic acids in specimens has made these methods accessible for many hospitals. Laboratories may combine both culture and nonculture approaches to optimize viral disease diagnosis, although many are eliminating culture in deference to the superior sensitivity, specificity, and turnaround times achievable by molecular methods. Table 252-2 summarizes optimal methods for the laboratory identification of specific viruses, and more in depth information is presented in the individual chapters of this book.

Virus Isolation

Culture remains the cornerstone to viral diagnostic testing and although not performed in all hospitals, is available in many reference and public health laboratories. Unlike rapid methods, which are limited to the detection of specific viral antigens or nucleic acids, culture is open-ended and permits the detection of unexpected or new viruses. In addition, a broad range of specimens can be evaluated, whereas rapid methods usually are approved or licensed for use with a limited number of specific specimens. Viruses that can be isolated in culture and identified readily include adenoviruses, HSV, VZV, CMV, enteroviruses, rhinoviruses, influenza and parainfluenza viruses, RSV, rubella virus, mumps virus, and measles virus. The number and type of isolates encountered depend on the patient population, season, and type of specimens submitted. For optimal laboratory diagnosis, indicating the name of the suspected virus on the requisition is important because some viruses require specific cell lines, procedures for identification, or both. Cultures are maintained for different time frames before finalizing a report of negative results, depending on the virus being sought; for example, HSV cultures usually are observed for 5 to 7 days, CMV for 1 month, and all others for 2 to 4 weeks. Improvements and modifications in culture methods have resulted in more rapid identification of isolates, with greater than 70 percent being reported within 5 days.[48,91]

Traditional Culture

For traditional culture, clinical samples are inoculated onto one or more cell lines, selected based on the submitted specimen and suspected virus. Cultures are observed at regular intervals for evidence of viral infection characterized by the appearance of cytopathic effect or the ability to hemadsorb or hemagglutinate RBCs. Adenoviruses, CMV, HSV, VZV, rhinoviruses, and enteroviruses can be identified and reported by their characteristic cytopathic effect. The mean time between inoculation of a specimen and the appearance of cytopathic effect usually is 1 week or less for most of this group, except CMV and some adenoviruses, which may require longer incubation. Cultures containing HSV and enteroviruses often are positive within 1 to 2 and 3 to 5 days, respectively. In the event of atypical or questionable cytopathic effect, immunofluorescence with monoclonal antibodies can be used to identify CMV, VZV, HSV-1, HSV-2, adenoviruses, enteroviruses, and some select coxsackieviruses and echoviruses in infected cell cultures. Although it rarely is performed, definitive identification of adenovirus and enterovirus serotypes by the neutralization test may be used if requested for epidemiologic or other reasons. More recently, molecular-based serotyping methods have been developed for both adenoviruses and enteroviruses with specificities equivalent to the neutralization test.[115,140]

Respiratory viruses, including parainfluenza and influenza viruses, which may or may not produce cytopathic effect, generally can be detected within 5 to 7 days of inoculation of the specimen with the traditional

TABLE 252-2 **Common Laboratory Methods for Diagnosis of Specific Viral Illnesses***

Virus	Culture	Antigen Detection	Serology	Nucleic Acid Amplification Test (NAAT)	Most Useful Method for Diagnosis
Adenoviruses	Routine	DFA ELISA	Reference or public health laboratory	Detected by some multiplexed respiratory virus assays Single-analyte commercial NAAT available	Culture or NAAT
Arboviruses of North America	Reference or public health laboratory	Not routine	Reference or public health laboratory	Reference or public health laboratory	Serology or NAAT
Coronaviruses	Not practical by routine methods (except SARS-CoV, which should not be cultured outside public health laboratories)	Not routine	Not routine	Detected by some multiplexed respiratory virus PCR assays	PCR
Rhinoviruses	Routine, must be differentiated from enteroviruses by acid lability	Not routine	Not routine	Detected by some multiplexed respiratory virus PCR assays	Culture or NAAT
Enteroviruses	Routine, some coxsackieviruses are difficult to culture by routine methods	Not routine	Not routine	NAAT from CSF routine Detected by some multiplexed respiratory virus NAATs	NAAT (especially from CSF) Culture
Cytomegalovirus	Routine	Not routine	Routine	Both qualitative and quantitative NAATs routine	NAAT Culture
Epstein-Barr virus (EBV)	Not practical by routine methods	Not routinely performed	Routine	Quantitative NAATs routine	NAAT

hemadsorption method, in which a suspension of guinea pig RBCs is added to the cell culture. The RBCs are observed to adhere to tissue culture cells infected with these viruses, usually 3 to 5 days after the inoculation of specimens for most isolates.[133] An adaptation of this method uses cell culture medium and guinea pig RBCs in a microtiter plate format to detect viral hemagglutinins in suspension. The results are similar to those observed with hemadsorption, but the adapted method is more rapid and simple to perform when screening numerous specimens.[98] RSV is identified presumptively, usually within 3 to 5 days of inoculation of the specimen, by its typical cytopathic effect (syncytium formation) and inability to hemadsorb and hemagglutinate guinea pig RBCs. This group of viruses is identified definitively by immunofluorescence with monoclonal antibodies.[64,176] The traditional method for isolation and identification of rubella virus uses primary African green monkey kidney cells in conjunction with the interference assay. After specified intervals following inoculation have transpired, cultures are challenged with a second virus, usually echovirus 11, incubated for an additional 3 to 4 days, and examined for cytopathic effect. The presence of rubella virus interferes with growth of the challenge virus, and no cytopathic effect is observed; on the other hand, if the challenge virus grows and produces cytopathic effect, the specimen is considered negative for rubella virus. Final identification of the isolate requires neutralization of the interference with specific rubella antibody.[176,204]

NAATs, serologic tests, or a combination of the two are recommended for viruses that are difficult or impossible to isolate in commonly employed cell lines or that require special techniques for detection of their presence. For instance, both NAAT and serology are useful for establishing the diagnosis of mumps virus. Although mumps virus can be isolated in the same cell lines used for other paramyxoviruses and detected by hemadsorption or hemagglutination, as previously described, such requests are rare. Buccal or oral swabs collected early in disease may be tested for mumps by a reverse transcription PCR assay. If negative, acute, and convalescent serum specimens may reveal diagnosis in patients with signs and symptoms of mumps. Similarly, most cases of arbovirus infection require the study of paired sera for antibody development for diagnosis. Human immunodeficiency virus (HIV) infection generally is identified best by the demonstration of serum antibody or antigen with the use of ELISA. Measles virus is relatively difficult to grow, and identification can take considerable time; when measles is suspected, the diagnosis is confirmed most easily by serologic study. Paired sera collected 1 week apart usually reveal a fourfold antibody titer rise. Alternatively, demonstration of specific IgM antibody allows the diagnosis to be established with the use of a single serum sample.

Modified Culture

A variety of physical and chemical methods have been evaluated for their ability to enhance the rapid detection of virus in culture.[91] These methods include the effect of low- and high-speed rolling of cultures, centrifugation, chemicals such as dimethyl sulfoxide, hormones such as dexamethasone, and enzymes such as trypsin on the isolation of viruses. A technique that entails the physical method of centrifugation with early antigen detection in cell culture and is termed variously the shell vial assay (SVA), the spin-amplified technique, or culture-amplified antigen detection is used routinely in most laboratories to decrease the time to detection of a positive culture. Cell lines are propagated on 12-mm round coverslips in 1-dram shell vials. An aliquot of specimen is inoculated into the vial, centrifuged at 700 × *g* for 1 hour, and incubated 1 to 3 days, depending on the virus being sought. Antigen typically is detected by immunofluorescence or occasionally by immunoperoxidase staining with monoclonal antibodies directed against a specific virus, before the appearance of cytopathic effect.

SVA was described initially and evaluated extensively for HSV* and CMV,† and its use since then has been extended to the rapid identification of VZV, adenovirus, RSV, influenza virus, parainfluenza virus, measles virus, and human metapneumovirus antigens in culture.[64] In addition, SVA has been applied to the detection of enteroviruses,[103,112] human herpesvirus type 6,[129] arboviruses (including dengue,[95] yellow fever, St. Louis encephalitis, West Nile,[95] and Venezuelan encephalitis equine virus).[24]

Pooled antibodies directed against seven commonly isolated respiratory viruses (i.e., adenovirus; influenza viruses A and B; parainfluenza virus types 1, 2, and 3; and RSV) also have been evaluated, and are commercially available.[123,146,161] To be adequately sensitive for each of these respiratory viruses, either two or more single cell lines in shell vial are used or mixed cell lines are applied to shell vial cultures. Mixed cell lines are particularly useful, in that they broaden the range of cultivable viruses, reduce the requirement for multiple single cell lines, and decrease the time to detection of a positive result and have sensitivity similar to that of conventional culture. The commercially available R-Mix (Diagnostic Hybrids) mixed cell line detects commonly isolated respiratory viruses. R-Mix consists of one cell line to support replication of RSV, adenovirus, and parainfluenza (e.g., A549) and another to support replication of influenza (e.g., Mv1Lu). R-Mix Too was developed after recognition that SARS-coronavirus (CoV) readily infected Mv1Lu cell lines[68]; R-Mix Too mitigates the possibility that SARS-CoV be inadvertently cultured in a routine clinical laboratory without appropriate biosafety precautions, by replacing Mv1Lu with MDCK cell lines.[68] R-Mix cells are available cryopreserved, with a shelf life of 6 months from date of manufacture, thereby enabling shipment to regions outside North America. Mixed cell lines are also useful for rapid isolation of human metapneumovirus[183] enteroviruses,[11,63,89] and herpes group viruses.[90] The sensitivity of mixed cell versus conventional single-cell lines for virus detection ranges from 92 to 100 percent for respiratory viruses[12,59,88,90,217] to 85 to

*References 23, 76, 117, 152, 160, 171.
†References 57, 72, 74, 75, 109, 151, 149, 162.

97 percent for enteroviruses,[63,89] with time to detection of a positive result reduced from an average of 5 to 10 days to 1 to 2 days for respiratory viruses and 1 to 3 days for enteroviruses.

Although rapid, sensitive, and specific, SVA is an adjunct to, and not a substitute for, traditional culture. In contrast to traditional culture, the sensitivity of SVA averages approximately 85 percent (range, 70% to 100%) and depends on numerous variables, including the cell line(s),[221] the age of cells,[57] the concentration of virus,[221] the type of specimen,[109,151] the number of vials inoculated,[151] and the type of reagents used.[55,76,130,152,171]

Other culture modifications include hybridization[55,61] and ELISA[9,47,127,203,209] for rapid detection of viruses. A modification of cell culture for the rapid detection of HSV is the enzyme-linked virus-inducible system (ELVIS).[186,187] This system consists of a mixture of modified baby hamster kidney cells and MRC-5 cells. The modified baby hamster kidney cells contain an HSV-inducible promoter and an *Escherichia coli* LacZ reporter gene that produces β-galactosidase only when cells are infected with HSV. After the addition of a substrate for the β-galactosidase, infected cells stain blue, whereas uninfected cells remain colorless. ELVIS appears to be comparable to culture for the detection of HSV-positive specimens (95% and 100% sensitivity) in a similar time frame, 1.4 to 1.7 days.[31,122]

Direct Detection

Cytology

Historically, rapid detection of viral infection relied on light microscopy and evaluation of tissues and exfoliated cells for viral inclusions or other cytopathic effects. Cytologic identification of virus is most useful in illnesses with vesicular exanthems such as HSV or VZV infection. A scraping of the base of an HSV or VZV lesion (Tzanck smear) reveals multinucleated giant and balloon cells when stained with hematoxylin and eosin, Wright, or Giemsa stain. In contrast, vesicular lesions caused by enteroviral infections do not contain giant or balloon cells, and allergy-related lesions contain eosinophils. Cytologic study of urine in congenital CMV infection reveals cells with the characteristic "owl's eye" intranuclear inclusions in 25 to 50 percent of cases, and nasal or pharyngeal smears in measles may reveal typical giant cells. These types of stains are no longer routinely performed in most diagnostic virology laboratories because they have been replaced by immunofluorescence, which is more sensitive and specific.[33,34] Whereas the Tzanck smear cannot differentiate HSV from VZV and the presence of multinucleated giant cells is necessary to make the diagnosis, immunofluorescence can identify the causative agent specifically and the presence of viral antigen in balloon or giant cells is diagnostic.

Antigen Detection

Antigen-detection methods are available for most commonly isolated viruses. Advantages of these methods include speed, standardized reagents and kits, the ability to detect nonviable, nonculturable, or difficult-to-grow viruses, and the ability to detect antigen when culture may be negative late in the course of infection. Generally, these methods are not as sensitive as NAAT or an optimized culture for viruses that can be cultured; thus, culture backup is recommended. These tests also are approved for specific specimen types. DFA, indirect immunofluorescent assay (IFA), and ELISA, are used most commonly for antigen detection in the clinical laboratory.

Immunofluorescence

Antigen detection by immunofluorescence requires collection of the appropriate cell types (i.e., those in which the virus propagates) in adequate numbers for evaluation. In some cases, the specimen is placed on the slide directly (e.g., HSV or VZV detection), but usually the sample is transported to the laboratory for processing and slide preparation (e.g., for respiratory virus detection). As is the case for all methods discussed in this chapter, the importance of adequate specimen collection cannot be overemphasized. When stringent specimen quality criteria are applied (e.g., ≥60 columnar epithelial cells per sample for influenza testing), DFA sensitivity approaches that of PCR.[156] However, such adequate specimens are infrequently collected, even when staff are trained in proper collection techniques.[110]

DFA methods use virus-specific monoclonal antibody labeled with fluorescein dye to detect antigen and usually require approximately 30 to 45 minutes to complete. If processing of the specimen is required and slides are prepared in the laboratory, additional time is necessary. For IFA, unlabeled monoclonal antibody is added to the sample and incubated for 30 minutes, followed by a wash and the addition of fluorescein-labeled anti-mouse immunoglobulin. After an additional 30 minutes of incubation has transpired and a wash step performed, the slide can be examined for typical fluorescence (for excellent photographic examples, see Rossier and colleagues[169]). IFA can be completed in 2 to 3 hours, depending on specimen-processing requirements and the number of viral antigens being sought. The advantage of using DFA or IFA is the ability to determine specimen adequacy and perform small-batch and demand testing. A high-quality microscope and skilled, experienced personnel are required for optimal preparation and evaluation of the specimen.

The first DFA reagent available for use in the diagnostic laboratory was for the detection of HSV[77] in genital, dermal, oral, and anal lesions. The test has not been validated for the detection of HSV in CSF, asymptomatic genital specimens, tracheal aspirates, or bronchoalveolar lavage (BAL) specimens. The sensitivity of DFA versus culture for HSV detection ranges from 72 to 92 percent[105,159] and, like culture, depends on the stage of the lesion.[33,34] DFA or culture detected HSV in 96.7 percent of vesicles, 79.2 percent of pustules, 44.7 percent of ulcers, and 16.7 percent of crusts.[33] In contrast, detection of HSV by NAAT is less influenced by lesion stage[58] and

may increase yield of a positive result in 13 percent of vesicles, 28 percent of ulcers, and 20 percent of crusts.[177] Nonetheless, lesion duration and morphology remain strongly associated with the likelihood of HSV detection by NAAT and negative results were obtained in 41.4 percent of vesicles, 48.4 percent of ulcers, and 76.9 percent of crusts.[177]

DFA is an excellent method for detecting VZV in vesicular lesion material. Because the virus is labile, the sensitivity of DFA is superior to that of culture,[30,49,73,175] and culture backup is not necessary. However, the utility of DFA in the post–varicella vaccine era is diminished by the fact that breakthrough disease in previously vaccinated patients presents as a macular or papular rash, from which virus-infected cells for DFA testing cannot be readily collected. In such instances, NAAT performed on a swab or scraping of the rash is associated with 95 to 100 percent sensitivity.[110,211]

Rapid detection of CMV antigen in lung tissue or BAL specimens[81,120,205,212] and in liver tissue[150] for the diagnosis of CMV pneumonia or hepatitis has been evaluated. The sensitivity is less than that of culture or SVA and ranges from 56 to 100 percent; results were best when a mixture of antibodies directed against early and late viral antigens was used.[205] Sensitivity may be reduced further because BAL specimens have virtually replaced lung biopsy for the diagnosis of CMV pneumonia. A comparison of the cellular portion, supernate, and whole BAL for isolation of CMV in culture suggested that in most BAL specimens, CMV is associated with the cell-free rather than the cellular component.[29] The antigenemia assay[199,200] is a sensitive, specific, and rapid method for detecting CMV viremia, but has widely been replaced in clinical practice by CMV DNA qualitative and quantitative PCRs, which are described below. The antigenemia assay consists of separation of leukocytes from whole blood, spotting or cytocentrifuging cells onto microscope slides, fixation and permeabilization, staining with monoclonal antibodies, and detection by fluorescein-labeled or peroxidase-labeled secondary antibodies. Antigen-positive leukocytes are quantitated.

Finally, DFA and IFA are useful for the rapid detection of common respiratory virus* in nasopharyngeal washes, aspirates, and suctions. DFA for RSV has been evaluated extensively,† and its sensitivity in contrast to that of optimized culture is 80 to 97 percent. As is the case for VZV, RSV is relatively labile, and antigen detection actually may be more sensitive than culture; thus, culture backup usually is not required. However, culture or multiplex NAATs may still be advisable because up to 30 percent of specimens submitted for establishing the diagnosis of RSV contain other viruses.[16,17,43] The sensitivity of DFA and IFA for detection of influenza virus A and B, parainfluenza virus 1, 2, and 3, and adenovirus antigens varies in contrast to that of culture (range, 29% to 100%‡), so culture or NAATs must also be performed for optimal diagnosis.

Enzyme-Linked Immunosorbent Assays

Standardized, well-characterized commercial kits for the detection of viral antigen by ELISA are available for HSV, RSV, influenza virus A and B, rotavirus, norovirus, adenovirus, HIV (p24), HTLV I and II, and hepatitis B virus (HBV). Intracellular and extracellular antigen can be detected; the methods are generally simple technically and are less affected by suboptimal specimen handling than are viral cultures. ELISAs come in two basic formats, either a classic microtiter or tube system or self-contained membrane assays. The microtiter or tube format uses antibodies lining the surface of the solid phase to capture viral antigen, which in turn is reacted with an enzyme-labeled secondary antibody, followed by detection with the addition of substrate and color development. Results are read spectrophotometrically and thus are objective, thereby eliminating some of the difficulties inherent in microscopic techniques, which require technical skill and expertise for evaluation of specimens. These tests are relatively inexpensive, can be automated, are suitable for processing large numbers of specimens, and generally can be completed within 2 to 4 hours. Specimens normally are batched and cannot be tested on demand, as previously described for immunofluorescence. In addition, the adequacy of the specimen cannot be ascertained. Membrane assays use the membrane as the solid support to retain viral antigen, to which enzyme-labeled antibodies are added to react with trapped antigen. Antigen-antibody complexes are detected via a chromogenic substrate, which is read visually. Although they are rapid (15 to 20 minutes) and simple to perform, these tests are more expensive, require more hands-on time, and do not result in objective end points. False-positive results and interpretation can be a problem. Detection of influenza and RSV antigens in nasopharyngeal aspirates, washes, suctions, and swabs has been evaluated extensively in standard and membrane ELISA formats.

Many of the membrane-based ELISA tests are Clinical Laboratory Improvement Amendments (CLIA)-waived; however, they may be performed in emergency departments, outpatient clinics, and physician offices for point-of-care diagnosis of influenza A and B and RSV in patients with compatible respiratory symptoms. However, the performance of these rapid ELISAs may vary significantly from the specifications listed in the package insert and year-to-year based on circulating virus type and subtype. The sensitivity of the BinaxNOW Influenza A&B was 75 percent for influenza A virus and 72 percent for influenza B during one influenza season, but only 48.9 and 36 percent, respectively, for a subsequent season, because of antigenic drift in the seasonal influenza virus.[69] Similarly, the reported sensitivity of various ELISAs to detect novel influenza viruses, such as the 2009 (H1N1) pandemic and the H3N2v 2012 influenza strains was 0 to 70 percent,* depending on test manufacturer. Because of these concerns, negative results always should be backed up by culture, immunofluorescence, or NAAT. The performance of the ELISAs also depends on the

*References 1, 2, 22, 56, 71, 92, 201.

prevalence of the virus among patients with febrile respiratory tract infections. When the prevalence of influenza in children with compatible symptoms was 5 percent, the predictive value of a positive rapid test was found to be 50 percent in contrast to reverse transcription polymerase PCR (RT-PCR) and the predictive value of a negative test to be 98 percent.[79] Conversely, when the prevalence of influenza was 21 percent, the positive predictive value was 85 percent and the negative predictive value was 91 percent.[79] Thus, for optimal diagnosis, these devices should not be used when disease prevalence is low or in the off-season. Contemporary performance of the rapid influenza ELISAs commercially available in the United States is summarized in Table 252-3.

Children shed high titers of RSV; therefore, membrane-based ELISA for RSV performs significantly better in the pediatric population than do the influenza tests. However, optimal performance is based on patient age and timing of specimen collection relative to onset of symptoms. The BinaxNow RSV was positive in 79 to 91 percent of children younger than 1 year of age in contrast to NAAT-confirmed or culture-confirmed RSV infection, but in only 52 percent of those 1 year of age and older[128] to 25 percent of adults.[145] The assay was positive in 92 percent of patients with 0 to 1 day of symptoms, 78 percent with 2 to 4 days, and 65 percent with 5 or more days of symptoms.[128] Similar to influenza, performance of RSV rapid antigen tests varies significantly year-to-year and with virus prevalence.[37] Commercially available RSV rapid antigen assays evaluated between 2007 and 2012 are summarized in Table 252-3.

For the diagnosis of rotavirus and adenovirus 40 and 41 infection, ELISA is the only rapid test available in the clinical laboratory. Rotavirus antigen detection by standard ELISA has been studied thoroughly.[53,56,162] Many of the assays have excellent sensitivity (93% to 100%) and specificity (98% to 100%) in contrast to that of electron microscopy, although the best results were obtained with monoclonal (vs. polyclonal) antibody-based kits (see elsewhere[57,195] for a review of available tests). Some assays can be read either visually or spectrophotometrically, so instrumentation is not always necessary. Several membrane enzyme immunoassays also are available for rotavirus antigen detection (e.g., TestPack and ImmunoCard) and, as is typical of this format, are somewhat less sensitive than standard ELISA, with approximately 10^7 virions/mL required for detection of a positive specimen. The reported sensitivity and specificity versus electron microscopy are 94 to 100 percent and 90 to 100 percent, respectively.[19,28,44] An excellent ELISA for detection of

*Performance characteristics were documented in publications between 2007 and 2012, for pediatric patients where data were available.
ND, Not done.

adenovirus 40 and 41 in stool specimens is available and yields a reported sensitivity, specificity, positive predictive value, and negative predictive value of 96, 96, 95, and 96 percent, respectively.[84,96,216]

Nucleic Acid Detection

Molecular methods for the detection, identification, and characterization of microorganisms are being adapted increasingly for use in the clinical laboratory. These assays provide a timely and specific diagnosis, although the cost of reagents can range from $30 to more than $200 per test. Nucleic acids may be detected either directly in clinical specimens via labeled DNA or RNA probes and hybridization or after amplification of selected nucleic acid targets and detection of the amplified product. Direct hybridization formats are no longer commonly employed in clinical laboratories and are not discussed herein. In contrast, NAATs are now widely used in virology laboratories of academic centers for routine diagnosis of viral infections. In these settings, NAATs were first developed in-house primarily for the identification of viruses that are not readily cultured (e.g., HSV from CSF) and for those in which time to detection by traditional means is too long to affect patient care (e.g., CMV). The past 5 years have witnessed an explosion in the number of NAATs for the rapid detection of all viruses commonly encountered in clinical practice. However, at the time of writing, the majority of laboratories continue to use suboptimal antigen tests for rapid viral diagnosis, in large part because of the cost of reagents and lack of expertise for molecular methods. However, contrary to this belief, when all costs are accounted for, including length of stay, frequency of diagnostic testing, and antibiotic use, diagnosis of respiratory viruses in children by a multiplex molecular method has been shown to be associated with cost savings equaling the cost of the assay or higher.[51,119]

Increased use of molecular testing for the diagnosis of viral infections has stimulated several recent developments, including automation of nucleic acid extraction, amplification, detection, and reporting and interpretation of results. Automation of specimen processing significantly improves extraction by rapidly and efficiently providing standardized, reproducible nucleic acids for amplification, comparable to those obtained with more labor-intensive manual methods.[52,135] Amplification and detection are integrated in real-time PCR and occur simultaneously, in contrast to conventional PCR, in which these processes are separate. Such systems also significantly reduce the opportunity for amplicon contamination. Finally, increased availability of commercial, mid- to low-complexity cartridge-based NAATs may facilitate molecular testing in smaller laboratories situated in community hospitals, emergency departments, or clinics, for rapid, near point-of-care testing.

In most cases, NAATs offer enhanced sensitivity and specificity over the other assays described in this chapter. However, clinical specimens sometimes contain inhibiting substances that interfere with the performance of NAATs. Internal control nucleic acids, generally in the form of bacteriophages or murine viruses, may be spiked into clinical specimens to monitor for inhibition. Additional limitations of NAATs are the potential for sample to sample or amplicon cross contamination, leading to false-positive results and the inability to distinguish between actively replicating virus and residual viral nucleic acids.

NAATs approved or cleared by the U.S. Food and Drug Administration (FDA) at the time of writing are discussed in the following sections with respect to their application for the diagnosis and monitoring of certain viral infections. The analytical and clinical performance characteristics of these tests are well defined, and these assays undergo routine quality assurance monitoring. Because the list of FDA-approved/cleared molecular assays is ever expanding, readers are directed to the Association of Molecular Pathology website* for a comprehensive up-to-date list of FDA-approved/cleared tests. In addition, laboratories may develop NAATs through use of analyte-specific reagents that are widely available for a variety of viral targets. These laboratory-developed tests can then be validated for clinical use in accordance with CLIA requirements, which must include assessment of accuracy or bias, precision, linearity, limit of detection, interfering substances, and stability. The sensitivity and specificities of these laboratory developed assays will vary across laboratories, and thus results from different laboratories cannot be used for comparison.

Single-Analyte Nucleic Acid Amplification Tests

Many single-analyte NAATs are available for detection of viruses in clinical specimens; these are listed in Table 252-4. NAATs are particularly useful for establishing the diagnosis when culture is too insensitive, lengthy, difficult, impractical, or unavailable. For example, NAATs on CSF are now the procedure of choice for diagnosis of HSV encephalitis,[194,197] despite the fact that no FDA-approved assays for the detection of HSV in CSF are currently available. Regardless, laboratory-developed CSF PCRs are commonly used for diagnosing HSV encephalitis, with reported sensitivity and specificity greater than 97 percent. These PCR-based methods are compared to a combination of traditional methods along with clinical observation and radiodiagnostic studies for case definition, because HSV rarely is recovered from CSF in culture. Further, PCR may be used for diagnosis even after start of acyclovir treatment. HSV can be detected by PCR of CSF in 98 percent of cases after 7 days therapy, 47 percent after 14 days, and 21 percent after more than 14 days.[167] Commercial HSV NAATs (Table 252-4) are also commonly used for detection of HSV DNA in skin and genital lesions and are associated with enhanced sensitivity in contrast to culture. NAATs are able to identify asymptomatic HSV, detect the presence of HSV for a longer period (in older lesions and even fixed tissue), and have greater diagnostic value than culture and clinical observations for assessing genital

HSV and treatment efficacy in patients with recurrent genital HSV.[32,45,83,136,137] NAATs also are useful for diagnosing ocular infections caused by specific viruses and supporting information in the clinical diagnosis of specific ocular disease syndromes.[94,219]

Similar to HSV, enterovirus is now commonly detected from CSF by NAAT because of slow growth or failure of certain serotypes to grow in culture. The sensitivity of the commercial enterovirus NAATs is 83 to 100 percent, whereas culture of CSF yields an isolate in only 36

percent of patients with enteroviral meningitis.[141] Xpert EV is a cartridge-based assay designed to be run on demand, in emergency departments, yielding results in a time frame suitable for making medical management decisions. Such assays are particularly helpful as CSF evaluation for pleocytosis is not always reliable for diagnosis of enteroviral meningitis because specimens with no pleocytosis may be culture-positive or PCR-positive.[168,172] The Xpert EV is associated with a sensitivity of 82 to 100 percent in contrast to laboratory developed assays.[42,139,141] A second commercial enterovirus NAAT licensed for use with CSF is the NucliSENS EasyQ Enterovirus assay (bioMeriuex), which is associated with similar sensitivity of 88 to 89 percent.[25] In contrast to the Xpert assay, which is an RT-PCR assay with real-time detection using Taqman probes, the EasyQ assay amplifies target enteroviral RNA by nucleic acid sequence–based amplification (NASBA). NASBA amplifies RNA under isothermal conditions, via simultaneous reverse transcription and T7 RNA polymerase to generate RNA copies of the enterovirus target. As the EasyQ enterovirus assay requires offline extraction of viral RNA from CSF and requires at least 5 hours to results, it is more suited to a central laboratory that is capable of performing high-complexity testing.

Single-analyte NAATs have been used for the qualitative detection of CMV, VZV, EBV, HBV, and human metapneumovirus from a variety of specimens. See Espy and colleagues[54] for a complete review.

Multiplexed Assays

Multiplexed assays for the detection of influenza A, influenza B, and RSV are listed in Table 252-4. These assays have the potential to replace DFA and rapid antigen tests as a sensitive and specific means by which to rapidly detect these viruses. The ProFAST, Simplexa Influenza A H1N1 (2009), Xpert Flu, and Verigene Respiratory virus Plus assays have the added benefit of providing a differentiation between the influenza A virus subtypes; this feature may aid in the recognition of new influenza A virus. All of the assays described in this section have excellent performance, with published sensitivities and specificities of more than 95 percent for their specific targets,* when performed per manufacturer instructions. The ProFAST (Gen-Probe) assays are multiplex real-time RT-PCR for the qualitative detection and discrimination of seasonal influenza A/H1, A/H3, and 2009 H1N1 viral nucleic acids. The assay targets the hemagglutinin gene and does not detect influenza B or C. In contrast, the ProFlu+ (Gen-Probe) assay targets the matrix gene for influenza A, the nonstructural genes NS-1 and NS-2 from influenza B, and the polymerase gene of RSV A and RSV B. In both assays, specimen is processed on an off-line nucleic acid extractor, and NAAT is performed on a Cepheid SmartCycler II instrument. The assay is based on Taqman chemistry, in which a target-specific probe with a 5′ fluorophore and a 3′ fluorescence resonance energy transfer (FRET) quencher anneals to the viral cDNA. While the probe is intact, fluorescence is quenched by FRET by the quencher molecule. However, during DNA amplification, the 5′ to 3′ exonuclease activity of Taq DNA polymerase cleaves the fluorophore from the probe, displacing it from the quencher, and allowing fluorescence. Assays for the detection of human metapneumovirus (Pro hMPV+), adenovirus (ProAdeno+), and parainfluenza (ProParaflu+) are also available from the Gen-Probe Prodesse line of assays. Like the Prodesse assays, the Quidel Molecular Influenza A+B uses Taqman chemistry in a real-time RT-PCR assay for the detection of influenza A and B.

The Verigene system is based on RT-PCR amplification of viral target nucleic acid, followed by detection via Nanosphere's proprietary gold nanoparticle hybridization technology. Amplicons from RT-PCR are hybridized to a microarray followed by silver-coated gold nanoparticle probe hybridization. Product is detected by light-scattering off the nanoprobes. Advantages of the test include minimal number of manipulations required by the technologist, for example, pipetting of specimens to the test cartridge at the start of the assay and removal to the reader at the end of the assay. However, throughput is low, with only one sample per processer. A second assay available as a sample-in, result-out format is the Simplexa Flu A/B & RSV Direct, a real-time RT-PCR assay performed on the 3M Integrated Cycler. This assay can be run in batches of eight samples per run. Also available is the Simplexa Flu A/B & RSV, in which extraction must be performed off-line, but which has a throughput of up to 96 samples. The Simplexa assays are based on scorpion probe chemistry. Scorpion probes consist of a 5′ fluorophore and 3′ quencher, which are held in close proximity by complementary sequences on the 5′ and 3′-end of the probe, resulting in a hairpin loop configuration. After PCR amplification, the probe sequence binds to its complement on the amplicon and this hybridization opens the hairpin loop such that fluorescence is no longer quenched. Sensitivity of the Simplexa Flu A/B & RSV Direct assay was reported for influenza A as 82 to 96 percent, influenza B, 76 to 99 percent, and RSV 95 to 98 percent.[5,179] Specificity is greater than 99 percent for all three targets.

Finally, the Cepheid Xpert Flu is a cartridge-based assay that uses real-time PCR with molecular beacon detection and is performed on the GeneXpert instrument. The assay is low-complexity, with less than 15 minutes hands-on time required to pipette the sample into the cartridge and start the assay; results are available in under 1 hour.

Highly Multiplexed Assays

Until recently, NAATs for infectious diseases testing were relatively simple, detecting at most eight targets because of limitations in specificity and detection of multiple analytes. However, in recent years, highly multiplexed NAATs have been developed for the detection of a wide variety of viruses that might be present in a single clinical sample, providing the key advantage of traditional culture. These assays also can detect multiple viral agents in a single specimen. These assays are best suited to sample

*References 5, 14, 46, 143, 157, 179, 180, 188.

types in situations in which a wide range of viruses may cause similar symptoms, such as with respiratory tract infections or gastroenteritis. To date, the highly multiplexed assays have been approved for use with respiratory specimens. The first diagnostic virus panel approved for use by the FDA is the xTAG RVP. The following virus types and subtypes are identified by the RVP: influenza A, influenza A subtype H1, influenza A subtype H3, influenza B, RSV A, RSV B, parainfluenza 1, parainfluenza 2, and parainfluenza 3 virus, hMPV, rhinovirus, and adenovirus. Viral nucleic acids are coextracted from nasopharyngeal swab specimens spiked with an internal control (MS2 phage), using an off-line automated extractor. Multiplex RT-PCR is then performed using primers specific to the viral targets and the control; these primers contain a tag sequence for target-specific primer extension (TSPE). The target-specific primers are then extended through addition of biotinylated deoxycytidine triphosphate to the reaction mixture, which is incorporated into the TSPE products. Following TSPE, products are mixed with color-coded microspheres with anti-tags. The anti-tag binds the tags present on the TSPE products, hybridizing the amplicons to the beads. The beads are read via solution-based microarray on the Luminex xMAP system by two lasers—the first identifies the virus-specific color-coded bead, the second determines whether amplicon is hybridized to the bead. The clinical performance of the xTAG RVP is well established (Table 252-5), but the assay has several limitations. Sensitivity for certain adenoviruses (species C, serotypes 7a and 41) is poor, and primers for detection of rhinovirus cross react with enterovirus. Furthermore, sensitivity for novel influenza A viruses is unknown. A second key limitation of this test is the risk for false-positive findings as a result of cross contamination by amplified nucleic acids, which are pipetted manually between stages of the assay. Additional limitations include time-to-results, which is 8 to 10 hours, and technical hands-on time. A second generation of the RVP was released in 2011, RVP FAST, which detects fewer analytes than the xTAG RVP, but has a

streamlined protocol with fewer manual steps and a turnaround time of 3 to 4 hours. The RVP FAST detects influenza A, influenza A subtype H1, influenza A subtype H3, influenza B, RSV, hMPV, rhinovirus, and adenovirus. The RVP FAST assay has reduced sensitivity for the detection of influenza B, possibly as a result of sequence variation in the primer binding region of the hemagglutinin gene among various strains.[148] The RVP FAST is also less sensitive for the detection of parainfluenza, and for this reason the target is not included in the FDA-approved version of the assay.

The FilmArray respiratory viral panel (Idaho Technology) is a fully closed system with a specimen-in, result-out format.[158] This sealed system minimizes the contamination concerns associated with the xTAG RVP assays. Viral nucleic acids are detected by a nested multiplex PCR; product is detected using end-point melting curve data on the FilmArray instrument. The assay requires little hands-on time, and results are available in just over 1 hour. A significant drawback of the system is the throughput, because only one sample can be processed on the instrument at a time. Thus, larger laboratories may need multiple instruments to meet test volume. The FilmArray is cleared for the detection of 15 viruses and subtypes, including those in the xTAG RVP in addition to human coronaviruses NL63, HKU1, 229E, OC43, and parainfluenza 4. Similar to the xTAG RVP assays, detection of adenovirus is problematic,[35,113,154] particularly species C; serotypes 2 and 6 are poorly detected (see Table 252-4).

Viral Nucleic Acid Quantitation Assays

Quantitative NAATs (qNAATs) play an important role in the diagnosis and management of viral disease. Viral load assays are used to predict disease progression, distinguish symptomatic from asymptomatic infection, monitor the development of antiviral resistance, and assess the efficacy of antiviral therapy. Table 252-6 lists the FDA-approved quantitative molecular assays currently available.

qNAAT assays for the management of HIV were the first to be used routinely for the early detection of infection, resolution of indeterminate Western blot results, evaluation of suspected prenatal and intrapartum infection, and monitoring of the viral load for prognosis and evaluation of therapeutic efficacy. The goal of antiretroviral therapy is a reduction of HIV-1 RNA below the limits of detection of the more sensitive assays (<20 to 75 cp/mL).[149,198,214] Detection and quantitation of serum HBV DNA can assist in diagnosis of early acute infection, distinguish active from inactive infection, and monitor response to antiviral therapy. In early, acute infection in which HBsAg is not detectable or yields equivocal results, detection of HBV DNA may be used to make the diagnosis. Viral load can predict the course of chronic HBV infection as well. Viral loads are high in chronic active, replicative infection in contrast to low or undetectable in chronic inactive infection. The aim of antiviral therapy is long-term suppression of viral replication; increasing HBV DNA levels may signal emergence of drug-resistant

TABLE 252-6 **U.S. Food and Drug Administration–Approved Quantitative Molecular Assays**

Target	Specimen	Linear Range	Method	Test Name	Manufacturer

CMV, Cytomegalovirus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *PCR,* polymerase chain reaction; *RT-PCR,* reverse-transcriptase PCR.

strains.[173] Detection and quantitation of hepatitis C virus (HCV) RNA is useful for establishing the diagnosis of acute hepatitis before seroconversion, for detection of chronic HCV in seronegative patients, for resolution of indeterminate serologic results, and to monitor patients for disease progression and response to therapy.* qNAATs are essential for management of chronic HCV. Viral load and genotype determine the likelihood of sustained viral response (SVR) and potential duration of treatment. Response to treatment is measured by achievement of SVR, defined as the absence of demonstrable viral replication 6 months after completion of a full course of treatment.

As is typical of other herpes group viruses, CMV possesses a high prevalence rate, establishes latency, and although usually asymptomatic in the normal host, causes disease in immunologically compromised hosts. Transplant recipients, patients with HIV or acquired immunodeficiency syndrome (AIDS), patients with cancer, and newborns are usually at highest risk for severe disease. Optimal patient management relies on laboratory testing. Quantitative assays are useful for early detection of CMV infection, differentiating latent infection from active disease, predicting disease progression, and monitoring response to antiviral therapy.[53,66,210,222] In general, higher viral loads correlate with risk for disease development and lower levels are associated with asymptomatic infection. Recommendations for serial monitoring using qNAATs have been published.[6,8,104] Generally, threefold to fivefold changes in viral load may represent a biologically significant change in viral replication. Viral load cutoffs correlate with change in patient management across transplant groups and laboratories because of variations in assay design and a former lack of a reference standard. The availability of an FDA-approved assay calibrated against the WHO international standard should clarify interpretation of results and aid in the establishment of significant viral load cutoffs within different immunosuppressed populations.

FDA-approved qNAAT assays do not exist for Epstein-Barr virus (EBV), BKV, and adenoviruses; however, quantitation of these viruses is routinely performed. As mentioned earlier, laboratory developed tests vary in assay design and thus yield results that cannot be compared across laboratories. No standardized cutoff values have been determined for the purpose of clinical management. Differences include specimen type and volume, nucleic acid extraction method, PCR primers and probes, amplification chemistry, calibrators used to create standard curves, and result reporting (copies per milliliter, copies per PCR, and copies per DNA concentration).

Conventional diagnostic methods generally are not useful in the evaluation of EBV-related disorders in immunosuppressed patients. Culture is not practical or useful, and serology is difficult to interpret in the setting of immunosuppression. PCR offers the possibility of rapid detection of EBV in a variety of clinical specimens and allows a semiquantitative or quantitative estimate of viral load. PCR has been used for establishing the diagnosis of AIDS-related central nervous system lymphoma,[66] EBV-related lymphoproliferative disorders,* and other EBV-associated diseases (e.g., infectious mononucleosis, fatal infectious mononucleosis, chronic active EBV infection, and EBV-associated hemophagocytic syndromes) in which increased DNA concentrations are associated with more severe clinical categories.[218] PCR is particularly useful for the early identification and diagnosis of lymphoproliferative disorders (e.g., posttransplant lymphoproliferative disorder [PTLD]) in pediatric patients after they have undergone liver transplantation, for monitoring EBV levels so that immunosuppression can be adjusted, and as a prognostic marker.† Viral load measurement of EBV is routinely used to diagnose or predict impending PTLD. High levels are nearly always associated with PTLD and increasing DNAemia predicts impending PTLD before appearance of signs and symptoms. Significant cutoffs range from 10^2 to 10^4 for serum and plasma and 10^3 to 10^4 for whole blood.[80]

Primary infection with BKV typically occurs in childhood and usually results in chronic, asymptomatic infection in immunocompetent individuals. Whereas clinical disease is rare in immunocompetent adults, BKV infections are a significant cause of morbidity and mortality in immunosuppressed patients, particularly in renal transplant recipients and those with hematologic malignancies. Disease manifestations in renal transplants include BKV nephropathy (BKVN), which may result in renal dysfunction and graft loss. Asymptomatic hematuria, hemorrhagic cystitis, and renal impairment may occur in bone marrow transplant recipients and patients with hematologic malignancy. BKVN affects 1 to 10 percent of renal transplant recipients with frequencies of graft loss between 10 to 80 percent within 5 years. BKV quantitative PCR can facilitate early diagnosis of BKVN, guide management of immunosuppressive therapy, and monitor response to intervention. Prospective studies have shown that high level BKV viruria (1 to 3 months after transplant) precedes sustained viremia (1 to 12 weeks before PVAN [polyomavirus-associated nephropathy]), which in turn precedes allograft dysfunction. Reduction of immunosuppression or treatment with cidofovir when the viral load reaches a specific level has been associated with improved clinical outcomes. BKV quantitative cutoffs that indicated the need for renal biopsy were DNA loads greater than 10^7 copies/mL in urine or plasma loads greater than 10^4 that persist for longer than 3 weeks.[15,107]

Human adenoviruses are associated with a variety of diseases affecting all organ systems. Most disease in immunocompetent individuals is self-limiting; however, severe or fatal disseminated disease may occur in bone marrow, stem cell, or solid organ transplant recipients. Treatment includes administration of cidofovir and reduction of immunosuppression. Viral load testing is increasingly being used to predict disease dissemination (>10^4 copies/mL) and monitor antiviral therapy, although viral load thresholds are still to be determined.[65]

SUMMARY

Methods for the laboratory diagnosis of viral infections, including culture, SVA, antigen detection, and molecular diagnostic methods, have been reviewed. The use of these tests in some combination is most practical because a single test may not yield a diagnosis. For many viruses, culture has been the gold standard or reference method for evaluation of the new, rapid tests. However, culture is neither 100 percent sensitive nor always diagnostic of symptomatic infection. With the newer methods, particularly molecular diagnostic methods, the gold standard is changing, and evaluation of new techniques must be compared against a spectrum of laboratory and clinical data. Standards for performance and guidelines for the use and interpretation of molecular techniques are becoming available. Quantitative (vs. qualitative) viral results may be useful for interpreting tests, particularly with regard to viruses causing latent infection or for monitoring therapy or disease progression. Finally, interpretation of any result requires integration of the clinical history, laboratory data, treatment records, and observation of trends over time.

CHAPTER 253

Parasitic Laboratory Diagnosis

David A. Bruckner • Robyn Shimizu-Cohen

Parasitic infections usually are associated with tropical areas; however, many infections (*Dientamoeba fragilis*, *Entamoeba histolytica*, *Enterobius vermicularis*, *Giardia lamblia*, and *Toxoplasma gondii*) have worldwide distribution. With the ability of travelers to move freely throughout the world in a short time span, clinical laboratories must be able to recommend specimen collection and detection/identification methods for all types of parasitic infections. It is helpful if the physician informs the laboratory of the parasitic infection that is suspected or the travel history of the patient because some organisms are detected more easily using specific methods (e.g., *Giardia* and *Cryptosporidium*—enzyme immunoassay [EIA] or direct fluorescent antibody [DFA] techniques) or alternative methods (e.g., microfilaria—Nuclepore filtration or Knott concentration procedure).[9,11,12] The life cycle of the parasite and the time of infection are important factors in determining the type of specimens to be collected and the techniques used to detect the infection (Table 253-1). Multiple specimens might have to be

examined before the etiologic agent can be detected (e.g., colon aspirates or biopsy tissue for *E. histolytica*, blood for malaria). All specimens must be considered infectious and must be handled with universal safety precautions using proper protective equipment.

The diagnosis of parasitic infections is dependent on macroscopic and microscopic examination of blood, feces, respiratory, tissue, and urine specimens. Specimens must be collected using methods that allow for the preservation of parasites when they are transported to the laboratory. Most stool specimens are collected at home or in a physician's office that may be a considerable distance from the laboratory performing the stool examination. Trophozoites disintegrate rapidly and do not form cysts after passage; therefore, stool specimens should be collected in containers from stool collection kits that have preservatives. The preservatives fix the specimens so that the trophozoites can be recognized easily on permanent stained slides and prevent the continued development of larvae and eggs.[3,11,13] Many laboratories have limited or no experience in detecting unusual infections such as malaria or filaria. It is recommended these specimens be sent to referral laboratories with greater experience.

If questions of when and how to collect specimens to maximize the recovery of parasites occur, the specific laboratory to be used should be consulted about the collection methods of choice.

STOOL SPECIMENS FOR DETECTION OF INTESTINAL PARASITES

Liquid or semisolid stool specimens should be examined within 30 to 60 minutes, respectively, from the time of collection for protozoan trophozoites. Because most clinical laboratories cannot perform the examination in this time frame, stool specimens should be placed in preservative immediately after passage (Table 253-2). Most stool collection kits contain a combination of vials such as sodium acetate–acetic acid–formalin (SAF) and polyvinyl alcohol (PVA); however, one-vial kits are becoming the system of choice.[3,11,13] Specimens should be collected before radiologic examination with barium is performed, which may prevent the detection of intestinal parasites for up to 10 days after administration. Other substances or medications that also can interfere with the detection of intestinal parasites for a prolonged period of time include antibiotics (aminoglycosides, metronidazole, and tetracycline), antimalarial agents, bismuth, mineral oil, and nonabsorbable antidiarrheal agents. The specimen should be collected in a clean, wide-mouthed container and must not be contaminated with toilet water or urine. Once collected, the specimen should be transferred to a container with preservative. After being mixed with the preservative, the specimen can be stored at room temperature until it is transported to the laboratory.

Physicians recommend that three specimens be collected on alternate days within 10 days to rule out most intestinal infections. The probability of detecting stool parasites with a single stool specimen is as low as 50 percent. Multiple specimens collected from the same patient on the same day should not be accepted. Many intestinal protozoa such as *Giardia* have a cyclical population cycle, and the concentration of trophozoites and cysts in the stool can vary considerably from day to day.

OTHER SPECIMENS FOR DETECTION OF INTESTINAL PARASITES

Sigmoidoscopy samples may be submitted for the detection of *E. histolytica*. No fewer than six samples (slides) should be submitted to the laboratory. Aspirates or scrapings can be collected and sent to the laboratory for direct wet mount observations, immunoassay, or polymerase chain reaction (PCR) (not commercially available). Preservatives such as Schaudinn fluid or PVA can be used to fix the samples to microscopic slides. Biopsy specimens should be submitted to the pathology laboratory for histologic preparation.

Duodenal aspirates and biopsy specimens can be collected for the detection of *Cryptosporidium*, *Giardia*, and *Strongyloides*. Collection techniques similar to those mentioned for the detection of *E. histolytica* can be used. In addition, duodenal contents may be sampled using the EnteroTest. The nylon string can be sent directly to the laboratory for processing and microscopic examination for parasitic organisms.

Strongyloides larvae might be detected in respiratory specimens during autoinfection or hyperinfection cycles. Serologic testing can be used to detect *Strongyloides* infections with low worm burdens.

E. vermicularis infections are detected best using the cellulose tape method. Specimens should be collected in the early morning before bathing or having a bowel movement. The adhesive side of the cellulose tape is pressed against the anal folds; and after completion of sampling, the tape is placed with the adhesive side down onto a microscope slide. *Enterobius* eggs and adults may be trapped on the tape (commercial collection kits are available).[3] Multiple specimens (four to six) may be collected on consecutive days to rule out the presence of infection. Eggs from infections with *Taenia* adult worms also may be detected using this method.

STOOL PROCESSING AND EXAMINATION FOR PARASITES

All specimens should be examined using a concentration technique and performing a permanently stained slide (Fig. 253-1). If fresh, unpreserved specimens are received, a direct wet mount should be performed for the detection of motile protozoan trophozoites and protozoan cysts. Helminth eggs and larvae also may be seen. If necessary, a few drops of saline may be used to emulsify the stool and a drop placed on a microscopic slide and covered with a 22 × 22-mm coverslip. The wet mount should be examined using 100× and 400× magnification. A drop of iodine solution may be added to highlight parasite internal structures; however, parasite motility will be lost. A concentrate and a permanent stained slide also should be prepared from this fresh specimen.

TABLE 253-2 **Common Intestinal Tract Specimen Preservatives**

Stool Preservative	Concentrate	Permanent Stain	Immunoassay	Advantages	Disadvantages
Formalin	Yes	No	Yes	Easy to prepare and has a long shelf life; preserves helminth eggs and larvae and protozoan cysts well; can be used with modified acid-fast and trichome stains; can be used with immunoassays.	Does not preserve trophozoite morphology adequately; not suitable for permanent stains; specimen does not adhere to slide.
MIF	Yes	No	No	Has a long shelf life; fixes and stains parasite forms simultaneously.	Two solutions must be mixed immediately before use; trophozoite morphology is poorly preserved; not suitable for modified acid-fast or trichrome stains; iodine interferes with immunoassays.
PVA	Yes	Yes	No	Excellent preservation of trophozoite morphology; suitable for PCR assays	Contains Hg making disposal quite costly; morphology of larvae and eggs makes identification difficult; unsuitable for modified stains; PVA interferes with immunoassays
PVA, modified	Yes	Yes	No	Does not contain mercury; disposal is less expensive	Copper or zinc (substitute for mercury) does not preserve trophozoite and cyst morphology as well as mercury, making identification difficult; PVA interferes with immunoassays.
SAF	Yes	Yes	Yes	Does not contain mercury; disposal is less expensive; has a long shelf life; permanent stain of choice is iron hematoxylin; preserves helminth eggs and larvae and protozoan cysts well; can be used with most immunoassays and special stains	Must use albumin-coated slides for permanent stains; contains formalin.
Schaudinn	No	Yes	No	Excellent preservation of trophozoite morphology	Contains Hg, making disposal quite costly; not recommended for concentrates and has poor adhesive properties for liquid and mucoid specimens.
Schaudinn, modified	Yes	Yes	Yes	Does not contain Hg, PVA, or formalin	Uses Zn as substitute for Hg. May need to coat slide with albumin for better specimen adhesion.

MIF, merthiolate-iodine-formalin; *PCR,* polymerase chain reaction; *PVA,* polyvinyl alcohol; *SAF,* sodium acetate–acetic acid–formalin.

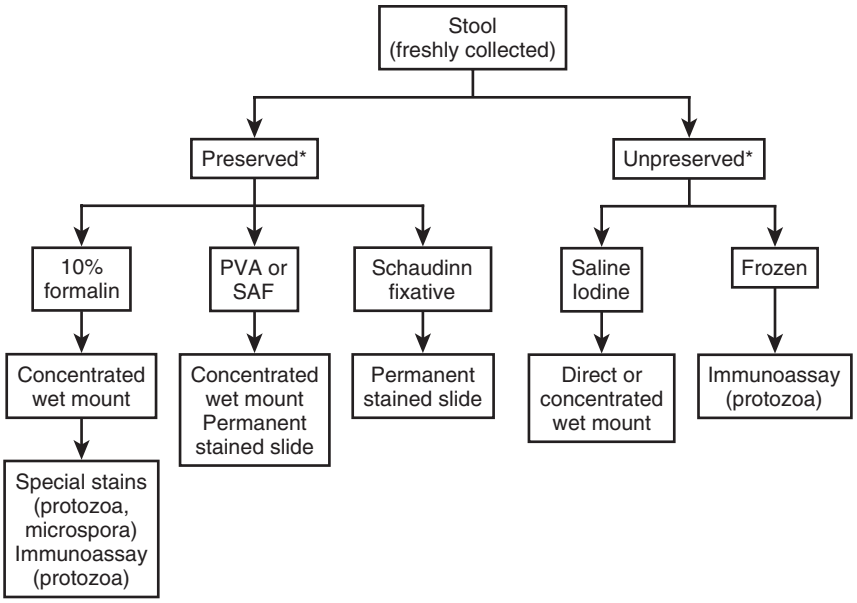

FIGURE 253-1 ■ Parasite stool examination. *Worms (cestodes, nematodes, trematodes)—fix in 70 percent ethanol. PVA, polyvinyl alcohol; SAF, sodium acetate–acetic acid–formalin.

Common concentration techniques include the flotation method using zinc sulfate ($ZnSO_4$) and the sedimentation method. Specimens fixed in formalin, merthiolate-iodine-formalin (MIF), PVA, SAF, or Schaudinn can be used. The flotation method gives a cleaner preparation to observe cysts and eggs, but the high specific gravity tends to distort cysts and eggs, rendering identification difficult. Heavier eggs (e.g., *Ascaris* or operculated eggs) will not float and will be found in the sediment; therefore, one should examine both top and bottom layers for a complete examination. The sedimentation method is used most widely in laboratories. Parasites and fecal debris are pelleted to the bottom of the tube by centrifugation. After the supernatant is discarded, the sediment is examined for parasites at 100× and 400× magnification.

Permanent stained slides should be prepared on every stool specimen that is examined for ova and parasites.[3,11,13] The stained slide is used primarily to detect and identify protozoa, trophozoites, and cysts. Gomori trichrome (Wheatley modification) and iron hematoxylin stains frequently are used in laboratories. Both stains have advantages and disadvantages that should be weighed, as should the expertise of laboratory personnel, before selecting the stain of choice for the laboratory.

Certain parasites are not detected easily by wet mount or routine permanent stained slides stained with Gomori trichrome (Wheatley modification) and iron hematoxylin. They include *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*, and microsporidia. The oocysts of *Cryptosporidium*, *Cyclospora*, and *Isospora* can be detected easily by the modified acid-fast stain. Microsporidia can be detected using a modified trichrome stain.[8,13]

Culture of fresh stool or contents of the large intestine have been used to detect *E. histolytica;* however, this methodology is not practical for most clinical laboratories.

EIA kits are commercially available for the detection of *E. histolytica/Entamoeba dispar* group, *G. lamblia*, and *Cryptosporidium*. For the *E. histolytica/E. dispar* group, only fresh or frozen stool can be used in the assay. Formalin interferes with reagents to detect *E. histolytica* and cannot be used. EIA kits are available that will discriminate between these organisms using fresh or frozen stool. EIA kits for the detection of *G. lamblia* and *Cryptosporidium* can be used with fresh, frozen, or formalin fixed stool. DFA tests have been developed to detect *G. lamblia* and *Cryptosporidium.* Depending on the manufacturer, either fresh or formalinized specimens can be used. PCR analysis also has been used to detect *E. histolytica*, *G. lamblia*, and *Cryptosporidium.* PCR test kits are not commercially available, whereas DFA and EIA kits are readily available. The DFA and EIA kits have excellent sensitivity and specificity compared with microscopy. The disadvantage of using DFA or EIA kits is that they detect only one or two pathogens at one time so other pathogens might be missed. Additional parasite examinations would have to be performed to detect other parasitic pathogens.

Detection of *Strongyloides stercoralis* is enhanced by culturing a small amount of fresh stool on an agar plate and looking for larval tracks across the plate, as evidenced by lines of bacterial growth.[4] Other methods include the Baermann concentrate, Harada-Mori, or Petri dish filter paper slant.[3,11,13] It is possible that hookworms eggs could hatch and the larvae would have to be differentiated from *Strongyloides* larvae.

BLOOD PARASITES

Numerous important parasites can be detected in blood, although most laboratories will see these organisms only during proficiency testing (Fig. 253-2).[6,7,10] These parasites include *Babesia*, *Leishmania donovani*, microfilaria,

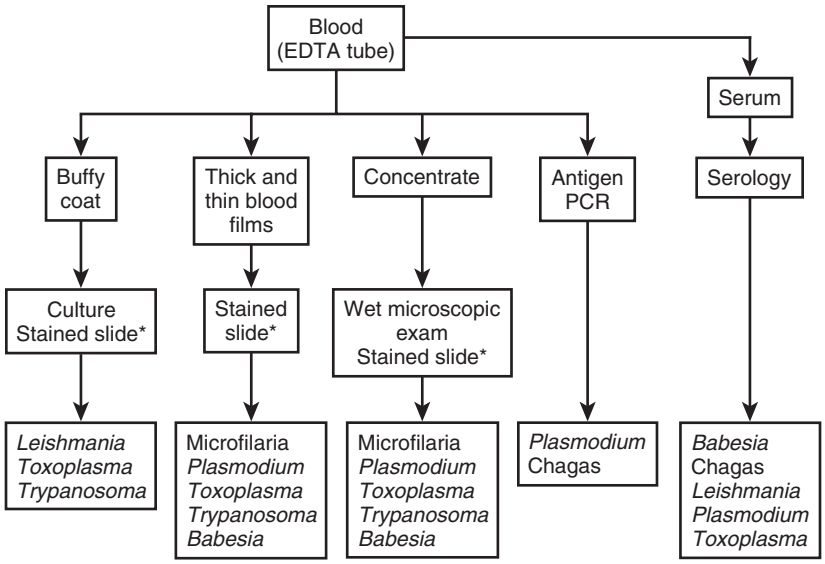

FIGURE 253-2 ■ Blood parasite examination. *Preferred stain is Giemsa; however, Wright stain is also acceptable. PCR, polymerase chain reaction.

Plasmodium, and *Trypanosoma*. They may be found in CSF, macrophages, plasma, tissue, or red blood cells depending on the parasite. Maintaining proficiency to speciate *Plasmodium* or to recognize the amastigote stages of *Leishmania* is difficult for many laboratory technicians because these infections are seen so infrequently in the United States. A very important factor is that the physician inform the laboratory personnel about the travel and medication history of the patient. If the patient took partial prophylaxis for malaria, a longer time should be spent examining the blood film owing to low parasitemia. Similarly, differences in periodicity of microfilaria in the blood exist and the timing of collection of specimens becomes more important. Alternative concentration techniques not normally used in most laboratories, such as Nuclepore filtration or the Knott concentration procedure, can be used to detect microfilaria in low numbers in the blood, and Nuclepore filtration also may be used with urine.[3,11,13] Without the knowledge of what infection the physician may be considering, these concentration procedures are not routinely performed on blood or other specimens and the diagnosis of infections could be delayed or missed. Requests for the diagnosis of malaria must be considered to be STAT requests owing to the morbidity and mortality mostly associated with *Plasmodium falciparum* infections.

Although some parasites (trypanosomes and microfilaria) can be detected by their motility in whole blood, identification is dependent on morphology as seen with a permanent stain. The blood film stain of choice is Giemsa, although Wright stain can also be used, or Delafield hematoxylin stain can be used for the microfilarial sheath. Because Giemsa stains may not differentiate the microfilaria nuclei adequately, Delafield hematoxylin stain may be necessary to speciate the microfilaria.

Although blood films can be prepared in clinics or at the bedside (finger or ear lobe sticks), the recommendation is that blood be collected in ethylenediaminetetraacetic acid (EDTA, lavender-topped tube) so that multiple slides (thick and thin blood films) may be prepared in the laboratory and concentration methods be used. EDTA-collected blood provides the best overall morphology of parasites, and the tubes should be filled to the proper level to reduce distortion of the blood cells and organisms by the anticoagulant. Heparin tubes (green-topped tubes) also can be used; however, these blood-filled tubes cannot be used for PCR testing. The blood should be examined for parasites within 4 to 6 hours of being collected.

Blood should be drawn immediately when parasitemia is suspected. For malaria, blood should be drawn every 6 to 8 hours for 36 hours to rule out infection. Pediatric patients may have blood samples drawn at 10-hour intervals. One set of negative blood films does not rule out the presence of malaria. When the parasitemia level is low, procedures other than thick films, such as antigen detection, serology, or PCR analysis may be the more sensitive method to detect *Babesia*, Chagas disease, malaria, or microfilaria.[7] Serology has not been shown to be an effective method to detect active infections of African trypanosomiasis in nonendemic areas.

Blood Processing and Examination for Parasites

If the physician does not indicate the specific blood parasite suspected, fresh blood should be used as a wet mount to look for the presence of microfilaria or trypanosomes by their characteristic shape and motility. If these parasites are detected, a permanent stained slide will have to be performed to identify the organisms to species. When thick and thin blood films are examined for the presence of parasites, no fewer than 300 microscopic oil fields should be examined before finalizing a result for the presence of *Babesia* or malaria. One may use lower magnification when looking for the presence of trypanosomes or microfilaria, but the entire film should be observed before finalizing a result. Thin films are used for the detection

of blood parasites, for enumeration of infected cells, and also to determine the species of parasite. Once the films are air dried, the film can be fixed with 100 percent methanol and stained with Giemsa stain or Wright stain without the methanol fixation process. If *Babesia* or malarial parasites (*P. falciparum* and *Plasmodium vivax*) are present, one should quantitate the number of infected red blood cells. This quantification can be expressed as the number of infected cells/100 red blood cells observed in the blood film. Serial specimens collected at various times during therapy can be used to monitor the success or failure of therapy. Continued presence of parasites in blood films without a marked decrease in parasitemia within the first 24 hours is an indication of therapeutic failure.

Thick films are prepared with one or two drops of blood that should be stirred in a small circle for 10 to 20 seconds at various intervals as it dries on the slide to prevent the blood from sloughing from the slide during the staining process. The thicker the film, the more likely the blood will slough. Detecting and identifying the presence of parasites on thick films is extremely difficult, particularly with inexperienced laboratory personnel. Once the thick film has dried, the blood film is laked with water or buffer before staining if Wright stain is used, or the films can be placed directly into Giemsa stain without prior laking. Laking disrupts the red cell membrane, allowing the hemoglobin to be removed and leaving parasites, white blood cells, and platelets intact. The search for microfilaria can be performed at a lower magnification, whereas the search for *Babesia*, malaria, and trypanosomes must be done with oil magnification looking at 200 to 300 oil microscopic fields.

Concentration techniques also can be used to detect *Babesia*, *Leishmania*, malaria, microfilaria, and trypanosomes. Microhematocrit capillary tubes can be centrifuged, and the parasitized red blood cells and trypanosomes can be detected near the buffy coat interface. The tube can be scored and snapped, and the buffy coat can be used to prepare a thin film. Alternatively, the tube can be observed under a microscope at the buffy coat interface for the presence of motile trypanosomes.

Microfilaria can be concentrated using the Knott procedure or Nuclepore membrane filtration technique. Normally, a 5-μm filter is used, but if *Mansonella perstans* microfilaria is suspected, a 3-μm filter is recommended. Most laboratories would not be familiar with or normally use concentration techniques unless specifically asked to do so.

Antigen tests for malaria have been developed and approved for clinical use in the United States.[5,7] These tests are extremely useful for laboratories that have limited expertise and exposure to specimens containing malaria or *Babesia*. It is difficult to differentiate malaria from babesiosis in patients with infections with very young trophozoites. In this situation, the malarial antigen test can be very helpful. The antigens detected in these tests include histidine-rich protein-2, lactate dehydrogenase, and aldolase. False-negative antigen test results are known to occur owing to mutations of histidine-rich protein-2 in *P. falciparum* infection. The sensitivity of the antigen tests to detect infections cause by *P. vivax*, *Plasmodium malariae*, or *Plasmodium ovale* is considerably reduced compared with *P. falciparum*. The histidine-rich protein-2 remains in the blood for a considerable period of time after therapy so it cannot be used to follow therapy.

UROGENITAL SPECIMENS

Trichomonas vaginalis is the most common pathogen; however, schistosome eggs, microfilaria, and microsporidium also may be recovered from urogenital specimens. Many *T. vaginalis* infections are diagnosed on clinical signs and symptoms without a specimen being collected. The detection of *T. vaginalis* usually is based on direct observation in wet mounts prepared from vaginal and urethral discharges, prostatic secretions, and urine sediment. Urine specimens should be obtained from first-voided urine in the morning. Specimens collected for the detection of *T. vaginalis* should not be refrigerated because *T. vaginalis* is susceptible to cold temperatures. Specimens can be diluted with a drop of saline and observed under low power in reduced illumination for the presence of motile flagellates. Stained slides, such as Giemsa or Papanicolaou smears, also can be used, but the majority of the infections with *T. vaginalis* are identified by the direct wet mount.

Culture (InPouch TV) can be used and is recommended by the Centers for Disease Control and Prevention (CDC) for patients suspected of harboring *T. vaginalis* infections when no organisms were detected by the direct wet mount method.[1] Specimens can be collected with a brush, swab, or sponge. Specimens should be inoculated as soon as possible into the media. Cultures showing no organisms after incubation for 4 days can be reported as negative. Commercially available DFA, EIA, and DNA probe kits have been approved by the U.S. Food and Drug Administration for the detection of *T. vaginalis*.[2,3,11,13] Alternative detection methods can be quite expensive owing to limited test utilization depending on the prevalence of infections in the area or community.

The Knott concentration procedure and the Nuclepore membrane filtration technique have been used for the detection of microfilaria in the urine. Microfilaria most frequently detected using these methods are *Wuchereria bancrofti* and *Onchocerca volvulus*.

Schistosoma hematobium eggs found in the urine can be concentrated by sedimentation, centrifugation, or the Nuclepore membrane filtration procedure. The preferred specimen is urine collected at midday, when the patient is most active and most likely to have eggs in the urine.

Serology

Definitive diagnosis of parasitic infections is usually made by detection of diagnostic parasite forms in blood, urine, other body fluids, tissue, or feces. A serologic diagnosis may be required when the parasites reside in tissues or other body sites and it is difficult to acquire a diagnostic specimen (e.g., in a patient with chronic Chagas disease or neural cysticercosis). Serology testing may also be

useful when parasites are in very low numbers in specimens and are difficult to detect (e.g., in a patient with strongyloidiasis, malaria, or babesiosis).

A positive serologic test in an individual who resides in an endemic area must be interpreted with caution because the result may reflect past exposure and be unrelated to current clinical condition. A positive test in an individual without any past exposure may indicate a recent infection; however, this result must be correlated with the patient's clinical picture.

The detection of IgA, IgE, IgG, and IgM antibodies to specific parasite antigens may or may not be helpful in establishing a diagnosis. With the exception of serology tests for the diagnosis of toxoplasmosis and the screening of the blood supply for antibodies to *Trypanosoma cruzi*, most of the other parasitic serology tests have limited laboratory availability. Although these tests will have been validated through in-house testing, except for *Toxoplasma* and *T. cruzi*, there are no established external proficiency testing programs such as those offered through the College of American Pathologists. Even though the test methodology may be the same between different laboratories, reagents used in the tests have not been standardized between laboratories if they do not use the same kit manufacturer. This can lead to varying results.

In the United States, most serologic tests for the diagnosis of a parasitic infection are limited to the most commonly acquired extraintestinal infections. These are available at a few referral laboratories, specialized testing centers and the CDC. Information on availability of parasite serology tests can be acquired from referral laboratories or from CDC.* The CDC offers the most comprehensive services for tests available and will also provide some information on unusual serologic testing not available in the United States.

OTHER SPECIMENS

Other important pathogenic parasites, such as ocular infections with *Acanthamoeba* and *Toxoplasma gondii*, can be detected in other anatomic sites and are addressed in specific chapters.

Yellow fever, 656, **2274-2278**
clinical manifestations of, 2275-2276
differential diagnosis of, 2276
Yellow fever *(Continued)*
epidemiology of, 2274f, 2275
historical perspective on, 2274
immunization against, 2277-2278, 3485-3487
laboratory diagnosis of, 2276-2277
pathology of, 2276
prognosis for, 2277
treatment of, 2277
Yellow fever virus, 2274-2275
Yersinia aldovae, 1531
Yersinia alecksiciae, 1531
Yersinia bercovieri, 1531
Yersinia enterocolitica, 1515-1516
adhesin A of, 1524
Ail protein of, 13, 1523-1524
animal reservoirs of, 1516-1517
antibodies against, 1529-1530
carriage of, 1518
enterotoxin of, 1525
injectisomes of, 1524
invasin of, 13, 1523-1524
iron metabolism of, 1525
plasmid-encoded factors of, 1524
type III secretion system of, 1524
virulence factors of, 1521-1526, 1522t-1523t
water contamination with, 1518
yersiniabactin of, 1525
Yops of, 1522t-1523t, 1524-1525
Yersinia enterocolitica infection (yersiniosis), **1514-1532**
adhesin A in, 1524
Ail protein in, 13, 1523-1524
asymptomatic, 1527-1528
bloodstream, 1528
clinical manifestations of, 607t, 612, 616t, 753t-756t, 1526-1528, 1526t, 1527f
community outbreaks of, 1518-1519
diagnosis of, 618, 1530
differential diagnosis of, 1529-1530
enterocolitis in, 1526-1527
epidemiology of, 1516-1519, 1517f, 1517t
extraintestinal, 1528
family epidemics of, 1519
food contamination and, 1517-1518
gastric acidity and, 1526
hepatic, 673
immune response to, 1521
incubation period in, 1518
invasin in, 13, 1523-1524
iron metabolism and, 1525
mesenteric adenitis in, 1520-1521, 1527
nosocomial, 1519
outbreaks of, 1518-1519
pathogenesis of, 13, 18, 1521-1526, 1522t-1523t
pathology of, 1519-1521
plasmid pYV in, 1524
postinfectious syndromes in, 1528-1529
prevention of, 1519
pseudoappendicitis in, 1527
reactive arthritis after, 1528
transfusion-related, 1518
transmission of, 1518
treatment of, 1530-1531
vulvovaginal, 569
water contamination and, 1517-1518
YadA protein in, 13
Yops proteins in, 18
Yersinia frederiksenii, 1531
Yersinia intermedia, 1531
Yersinia kristensenii, 1531
Yersinia massiliensis, 1531
Yersinia mollaretii, 1531

Yersinia pestis, 1509-1510
toxin of, 1511-1512
Yersinia pestis infection (plague), **1509-1514**
bioterrorist, 3583-3584
Caf1 in, 5
cervical lymphadenopathy in, 177, 180
clinical manifestations of, 753t-756t, 1512-1513
diagnosis of, 1513
differential diagnosis of, 1513
epidemiology of, 1509, 1511
historical perspective on, 1509
localized (pestis minor), 1511
nosocomial, 3401
pathogenesis of, 1511-1512
prevention of, 1513-1514
prognosis for, 1513
septicemic, 1512
transmission of, 1510-1511
treatment of, 1513
Yersinia pseudotuberculosis, 1515-1516
invasins of, 13
type III secretion system of, 1524
virulence factors of, 1521, 1522t-1523t
YadA of, 13
Yersinia pseudotuberculosis infection (yersiniosis), 1068, **1514-1532**
clinical manifestations of, 753t-756t, 1529
diagnosis of, 1530
differential diagnosis of, 1529-1530
Yersinia pseudotuberculosis infection (yersiniosis) *(Continued)*
epidemiology of, 1519, 1520f
immune response to, 1521
Kawasaki disease–like illness in, 1529
mesenteric adenitis in, 1521
pathogenesis of, 1521-1526, 1522t-1523t
pathology of, 1521
septicemic, 1529
treatment of, 1530-1531
Yersinia rohdei, 1531
Yersinia ruckeri, 1531
Yersinia spp., 1515-1516
identification of, 1530
typing of, 1515-1516
virulence factors of, 1521-1526, 1522t-1523t
Yersinia spp. infection, **1514-1532.** *See also specific species infections*
epidemiology of, 1516-1519
historical perspective on, 1514-1515
uveitis after, 816
Yops proteins, 18, 1522t-1523t, 1524-1525

Z

Zanamivir, 3268t, 3270-3273, 3270f
in community-acquired pneumonia, 290
in influenza virus infection, 2348-2351, 2349t
in laryngotracheitis, 257
Zeaxanthin, 77
Zidovudine, 2612
Zika fever, 749, **2316-2317**
Zinc
deficiency of, 77t, 79
in gastrointestinal tract infection, 625-626
metabolism of, 77t, 78-79
Zinc lozenges, in common cold, 138
Zonisamide, pancreatitis with, 691
Zoster, **2021-2033**
clinical manifestations of, 2027-2028, 2027f
complications of, 2027-2028
diagnosis of, 2028
epidemiology of, 2023-2024
immunization against, 2023-2024
pathogenesis of, 2024-2025
prevention of, 2030-2032
prognosis for, 2029-2030
risk factors for, 2023-2024
after solid-organ transplantation, 979
transmission of, 2023
treatment of, 2028-2029
Zygomycetes, 2837, 2838f. *See also* Entomophthorales infection (entomophthoromycosis); *Mucor* spp. infection (mucormycosis); Rhizopus spp. infection (mucormycosis)
epidemiology of, 2837-2839, 2839f
neonatal infection with, 899

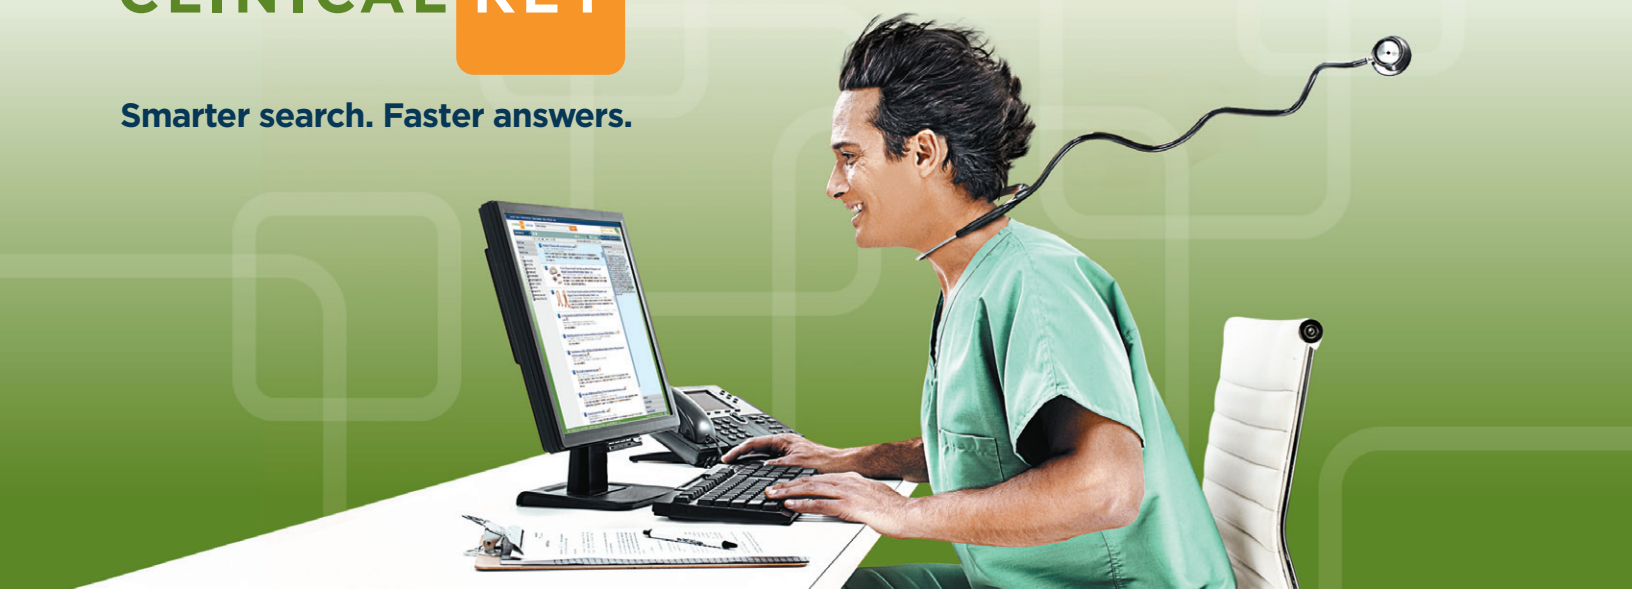
CLINICAL KEY™

Smarter search. Faster answers.



Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ***ClinicalKey.com*** for more information and subscription options.
